INDEX TO VOLUME CXLII.

Abbott. Report of a few cases of insanity treated by the cold pack, 164, 197.

Abbott, A. C. Relative infrequency of acute transmissible diseases during the first year of childhood, with a discussion of the probable reasons for the same, 543.

Abbott, S. W. Sixteen years' experience in food and drug inspection, 82; progress in public hygiene, 330, 356, 380, 432.

Abdomen. On the advisability of a more or less general exploration of the abdomen when it has been opened for an operation, Homans, J., 189; remarks on the influence of technique upon the results of closure of wounds of the abdominal wall, Noble, C. P., 237, 256; a case of acute general peritonitis, operation, recovery, Mumford, J. G., 301; gunshot wound of the abdomen, with multiple wounds of the intestine, Lothrop, H. A., 405, 413.

Actinomycosis. The organism and lesions of actinomycosis, Wright, J. H., 545.

Addison's Disease. Case of Addison's disease under treatment with suprarenal extract, Johnston, W. W., 549.

Africa. The wounded in South Africa, 95; military surgery in South Africa, 118; the war in South Africa, Treves, F., 151; expense of medical consultants in South Africa, 343.

Alcohol. The controversy as to the nutritive value of alcohol, 258; alcohol in the tropics, 672.

Allis, O. H. Dislocations of the hip, demonstration on the cadaver illustrative of their mechanism, 606.

Allis's method of reducing a dislocation of the hip, Warren, J. C., 40.

Amputation. A case of Chopart's amputation, with tendon implantation and tenotomy, Mumford, J. G., 301.

Anders, J. M. The diagnostic value of tuberculin in tuberculosis, 573.

Anemia. Anemia and other diseases in Puerto Rico, 393; some of the conclusions arrived at after a study of 110 cases of pernicious anemia, Cabot, R. C., 546; a report of cases of pernicious anemia, with a special reference to the blood findings, Billings, F., 546; clinical notes on cases of pernicious anemia, Henry, F. P., 546.

Angiotribe. The use of the angiotribe, Goffe, J. R., 373.

Animals. Adaptation of pathogenic bacteria to different species of animals, Smith, T., 473.

Anopheles and malaria, Colli, 261.

Appendicitis. Appendicitis in a hernial sac, Tenney, B., 4, 12; the attitude of the physician and surgeon to appendicular symptoms complicating typhoid fever, Hare, H. A., 556; observations on appendicitis, Van Giesen, I., 550.

Argentina. Heat in Argentina, 394.

Army. The best diet for the tropics, the army ration, 47; report of the Surgeon-General of the Army, 118; acting assistant surgeons in the Philippines, 178; contract surgeons, 416; the ideal ration for an army in the tropics, Munson, E. L., 463, 489, 501, 534.

Athens. Hydrophobia in Athens, 314.

Atwood, C. A. A pistol wound of the abdomen, 39.

Austin, A. E. A method of determining the digestive power of gastric juice as well as the absorptive power of the stomach, 246.

Bacillus. Varieties of the diphtheria bacillus, Westbrook, F. F., 518; clinical report of cases of infection due to the bacillus aërogenes capsulatus of Welch, Thorndike, P., 592; report of cases in which the bacillus aërogenes capsulatus was found, Pratt, J. H., and Fulton, F. T., 599.

Bacteria. Adaptation of pathogenic bacteria to different species of animals, Smith, T., 473; bacteriotherapeutics, with especial reference to tuberculosis, Baldwin, E. R., 477; the relation of bacteriology to medicine, Cabot, R. C., 479; bacteria and the buried animal body, 578.

Baldwin, E. R. Bacteriotherapeutics, with especial reference to tuberculosis, 477.

Baldwin, H. C. The work of the trustees of the Boston Insane Hospital and their plans for its future development, 379, 383.

Baldwin, L. G. Malignancy in the female genito-urinary system, 66.

Bartlett, E. A Rhode Island philosopher, Osler, W., 49, 77.

Barton, J. M. Fractures of the patella, 698.

Beach, H. H. A. Anatomical specimens, 11; intestinal obstruction, 110.

Beck, C. Surgical errors in skiagraphy, 686.

Bell, A. N. Stamina, the special benefit of fats of one kind or another as a nece sary article of diet to fortify the system against tubercle bacilli, 574.

Bequests. The dispersion of bequests, 94.

Bernays, A. C. On ischemic paralysis and contracture of muscles, 539.

Bevan, A. D. Unreduced and irreducible dislocations, 698.

Bibliography. Ashby, H., the diseases of children, medical and surgical, 701; Barker, L. F., the nervous system and its constituent neurones, 68; Bartholow, R., a practical treatise on materia medica and therapeutics, 93; Bradford, E. H., and Lovett, R. W., treatise on orthopedic surgery, 361; Brown, H., ringworm and some other scalp affections, their cause and cure, 521; Butler, G. P., a text-book of materia medica, therapeutics and pharmacology, 240; Cattell, H. W., international clinics, 551; Christison, J. S., brain in relation to mind, 257; Church, A., and Peterson, F., nervous and mental diseases, 116; Collins, H. D., and Rockwell, W. H., Collins's and Rockwell's physiology, 281; Corwin, A. M., essentials of physical diagnosis of the thorax, 281; Crockett, M. A., Crockett's gynecology, 236; cyclopedia of the diseases of children, medical and surgical, 69; Deaver, J. B., surgical anatomy: a treatise on human anatomy in its application to the practice of medicine and surgery, 117; Dudley, E. C., diseases of women, 147; Fitzgerald, J., pyorrhea alveolaris and its relation to general medicine, 146; Foxwell, A., the causation of functional heart murmurs, 436; Fullerton, A. M., surgical nursing, 281; Gillespie, A. L., a manual of modern gastric methods, chemical, physical and therapeutical, 338; Gould, G. M., the American year-book of medicine and surgery, 200; a pocket medical dictionary, 281; Gowers, W. R., a manual of diseases of the nervous system, 17; Gruenwald, L., atlas and abstract of the diseases of the larynx, 309; Haig, A., diet and food, 310; Hall, T. W., and Menzies, J. A., golden rules of physiology, 281; Hall, W. S., a text-book of physiology, 521; Harrison, E., home nursing, 362; Harrison, R., selected papers on stone, prostate and other urinary disorders, 93; Harvard University, annual report, 201; Head, G. E., and Andrews, A. H., the year-book of the nose, throat and ear, 338; Hewer, L., our baby, 701; Holland, J. W., the urine and the clinical chemistry of the gastric contents, the common poisons and milk, 310; Hughes, D. E., a compend of the practice of medicine, 362; Hyde, J. N., and Montgomery, F. H., a practical treatise on diseases of the skin for the use of students and practitioners, 551; international medical annual and practitioner's index, 438; Keen, W. W., and White, J. W., an American text-book of surgery for practitioners and students, 280; Keyes, E. L., and Chetwood, C. H., venereal diseases, 522; Knopf, S. A., prophylaxis and treatment of pulmonary tuberculosis, 437; Kyle, D. B., a text-book of the diseases of the nose and throat, 360; Lewis, T. B., a text-book of mental diseases, with special reference to the pathological aspects of insanity, 70; Lilienthal, H., imperative surgery for the general practitioner, the specialist and the recent graduate, 280; Longeway, M. L., the trained nurses' directory, 70; Lucas, J. J. S., Nordrach at home, or hygienic treatment of consumption, 310; Maisbery, L. E., practice of medicine, 362; Massachusetts Board of Insanity, first report, 551; McKendrick, J. G., Herman Ludwig Ferdinand von Helmholtz, 229; Mills, C. K., the nervous system and its diseases, 17; Monro, T. K., Raynaud's disease (local syncope, local asphyxia, symmetrical gangrene), its history, causes, symptoms, morbid relations, pathology and treatment, 94; Moullin, C. M., epididymectomy of the prostate, its true and radical cure, 92; Netter, la peste et son microbe, 414; Park, W. H., bacteriology in medicine and surgery, 229; Pedley, R. D., the hygiene of the mouth, 117; Penrose, C. B., a text-book of diseases of women, 281; Phelps, E. S., loveliness, 172; Purrington, W. A., Christian Science, 338; Quarantine and national report of the Board of Health of the Province of Quebec, 361; Roberts, J. B., notes on the modern treatment of fractures, 281; Schweinitz, G. E. de, an American text-book of the diseases of the eye, ear, nose and throat, 92; Stedman, T. L., twentieth century practice, 171, 437; Talbot, E. S., interstitial gingivitis, or so-called pyorrhœa alveolaris, 171; Thorington, J., refraction and how to refract, 236; Truax, C., the mechanics of surgery, 280; Valentine, F. C., the irrigation treatment of gonorrhea, local complications and sequelæ, 609; Voswinkel, B. M., surgical nursing, 93; Warren, J. C., and Gould, A. P., the international text-book of surgery, 257; Watson, C., encyclopedia medica, 172; Watson, J. K., a hand-book for nurses, 575; Wharton, H. R., minor surgery and bandaging, 94; Ziegler, A., general pathology, 171.

Billings, F. A report of cases of pernicious anemia, with a special reference to the blood findings, 546.

Biography. Apostoli, 643; Arrowsmith, J. E., 76; Bagg, M. M., 528; Bailey, T. H., 316; Bartlett, E., 49, 77; Bartlett, G. P., 365; Beebe, A. A., 316; Beebe, C. E., 284; Bill, H. P., 288; Billings, A. J., 179; Birch-Hirschfeld, 441; Bird, J. S., 396; Bronson, J. R., 528; Carsen, W., 179; Clark, R., 469; Collins, C. S., 580; Conklin, G. H., 420; Cook, J. S., 76; Cooper, J., 368; Crane, J. J., 444; Cresmer, J. M., 236; Edwards, A. M., 643; Ellis, G. V., 643; Fitzsimmons, T. D., 179; Forman, S. R., 230; French, G. M., 236; Garrison, S. O., 444; Gehring, F. H., 76; Gibier, P., 645; Graves, F. W., 288; Gray, L. C., 527; Hall, M. W., 76; Hammond, W. A., 41; Harrington, J. C., 444; Harris, R., 344; Hassie, T. B., 444; Hastings, W. H. H., 208, 234, 314; Helmholtz, H. L. F. von, 229; Hoffman, J. B., 344; Holmes, E. L., 208; Hopkins, W., 30; House, W. S., 124; Howard, B. D., 701; Howard, W. F., 704; Hubbard, O. P., 288; Kimball, F. D., 420; Kingsley, C., 48; Leonard, E. K., 674; Lindström, A. H.,

536; MacDonald, J., 580; Maclagan, A. D., 468; Malone, S., 20; Marsh, A., 154; Martin, E. F., 236; Mersereau, C. H., 528; Metcalf, E. G., 154; Morse, L. R., 580; Mivart, G., 364; O'Callaghan, T., 24; O'Hearn, W. H., 614; Otis, F. N., 579; Paget, J., 22, 24, 43; Peck, A. E., 288; Pennington, S. H., 316; Perkins, E. A., 236; Pettingill, F. H., 179; Pierce, G. C., 580; Pierson, W., 676; Plunkett, F. C., 153; Priestly, W. O., 417; Prince, C., 288; Richardson, A. P., 154; Rightmore, W. V., 179; Shakespeare, E. O., 614; Shaw, J. C., 124; Stackpole, P. A., 368; Stewart, T. G., 154; Stickler, J. W., Jr., 206; Storrs, M., 674; Vondy, J. H., 396; Voorhees, C. H., 556; Wamsley, W. E., 264; Warren, G. W., 528; Whistler, W. M., 316; Woodbridge, L. D., 46; William, C. C., 124; Winston, G. S., 24.

Blake, C. J. The sociological status of the physician, 482.

Blake, J. D. Tetanus treated with antitetanic serum, 690.

Blanchard, W. Rapid osteoclasis for the correction of rhachitic deformities of the legs, 664.

Blodgett, A. N. Lithiasis preputialis, 675.

Blood. The practical value of the white blood count in surgical cases, Hubbard, J. C., 409, 412; examination of the blood, its value to the general practitioner, Fussell, M. H., 638.

Boland, E. S. Idiopathic pneumohematothorax with recovery after aspiration, 321, 333.

Bonney, S. G. Some phases of the tuberculosis problem in Colorado, 572.

Bowditch, H. P. The medical school of the future, 445; Dr. Bowditch's address, 468.

Bowditch, V. Y. The Massachusetts State Hospital for Consumptives at Rutland; its purposes and the work accomplished during the first year, 127, 142.

Bowen, J. T. Report on dermatology, 193.

Bradford, E. H. Results of treatment of congenital dislocation of the hip, 630.

Bradford, E. H., and Brackett, E. G. Report on orthopedic surgery, 223.

Bradycardia, with intermittent albuminuria, Whitridge, A. H., 329.

Brewster, G. W. W. A case of intestinal obstruction from a hair-ball, 395.

Bridge, N. Some observations on human temperature in disease, 550.

Brothers, A. Some points in the diagnosis and management of cystitis in the female, 357.

Bryant, J. D. Malignant disease, 65.

Bullet. The "humane" bullet, 364.

Burns, W. B. Malarial hemoglobinuria, 668.

Burr. C. B. Intestinal digestion and its relation to pulmonary disease, 101.

Burr, W. The relations of chorea and rheumatism, 669.

Burrage, W. L. Abstract of paper on "further experience with the operative treatment of anteflexion," 241, 255; abdominal myomectomy, removal of eleven subperitoneal nodules and right ovary weighing together one and one-half pounds, 349; the conservative operative treatment of fibroids, report of three cases, 349, 358; vaginal myomectomy, removal of fibroid nodule three centimetres (one and one-fourth inches) by one and one-half centimetres (seven-eighths inch), of subperitoneal evolution from the front wall of the uterus by anterior colpotomy, 349; morcellation of submucous nodule at fundus and polyp with pedicle springing from fundus, 350.

Burrell, H. L. A personal experience in the teaching of surgery, 565, 568.

Cabot, A. T. Adhesions of the stomach, 606; realism in medicine, 615, 647.

Cabot, R. C. Some points suggested by the clinical study in one hundred and eighty-six cases of valvular heart disease, 106, 111; a second case of chronic cyanosis without assignable cause, 275; splenic pseudoleukemia, historical sketch, 421, 435; double extrauterine pregnancy, 428; the relation of bacteriology to medicine, 479; some of the conclusions arrived at after a study of 110 cases of pernicious anemia, 546.

Camac, C. N. B. Hospital and ward clinical laboratories, 637.

Cannon, W. B. The case method of teaching systematic medicine, 31; the case system in medicine, 563, 568.

Cary, C. Dogenerated echinococcus cyst of the pleura, 550.

Case method of teaching systematic medicine, Cannon, W. B., 31; the case method of teaching medicine, 42.

Cats. Sympathy for cats, 90.

Cells. Anopheles and malaria, 261.

Centenarian. A centenarian, Cummings, A. R., 207.

Chase, R. F. Bradycardia, with a report of a case, 130, 140.

Children. Three cases of angioneurotic edema in infancy, Morse, J. L., 10; the proper seating of school children, 339; hair-eating children and convulsions, Lyon, F. D., 345; measurements of Boston school children, 526; relative infrequency of acute transmissible diseases during the first year of childhood, with a discussion of the probable reasons for the same, Abbott, A. C., 543; recurrent vomiting in children, Griffiths, J. R. C., 544; heart lesions in infancy, Jacobi, A., 571; exercises suitable for children suffering from heart disease, Taylor, J. M., 574.

Cholecystostomy. Cases of cholecystostomy, Garceau, E., 104.

Christian Science a menace to the public weal, 283, 285.

Circulatory System. Epistaxis, Cobb, F. C., 2, 12; the value of x-ray examinations in the less frequent diseases of the chest illustrated by their use in those cases where aneurism is present or suspected, Williams, F. H., 54, 85; some points suggested by the clinical study in one hundred and eighty-six cases of valvular heart disease, Cabot, R. C., 106, 111; bradycardia, with report of a case, Chase, R. F., 130; the clinical value of Oliver's hemocytometer, Scannell, D. D., 160; a second case of cyanosis without assignable cause, Cabot, R. C., 275; report on progress in thoracic diseases, Sears, G. G., and Bartol, J. W., 276, 302; bradycardia with intermittent albuminuria, Whitridge, A. H., 329; the practical value of the white blood count in surgical cases, Hubbard, J. C., 409, 412; cyanosis from congenital cardiac disease, Townsend, C. W., 436; venous thrombosis as a complication of cardiac disease, Welch, W. H., 549; aneurism of the aorta with rupture into the superior vena cava, recognized during life, Stengel, A., 550; minor forms of cardiac dilatation, Robinson, B., 550; heart lesions in infancy, Jacobi, A., 571; the blood changes in high altitudes, Solly, S. E., 574; a case of mural endocarditis, Williams, H., 574; exercises suitable for children suffering from heart disease, Taylor, J. M., 574; aneurism of heart, thrombosis of left coronary artery, Daland, J., 575; examination of the blood, its value to the general practitioner, Fussell, M. H., 638; rheumatism and the prevention, of heart complications, Walsh, J. J., 669; heart in rheumatism, Rochester, Del., 669; a case of malignant endocarditis with recovery, Davis, N. S. Jr., 670.

Clark, J. P. Anatomical specimens, 435.

Cleveland. Ruptured ovarian cyst, 337.

Cobb, C. M. A new nasal scissors for the removal of the lower turbinate, 603.

Cobb, F. C. Epistaxis, 2, 12.

Coley, W. B. The treatment of inoperable malignant tumors, 68.

Consultants. Expense of medical consultants in South Africa, 343.

Consultation. The physician and the surgical consultant, 70.

Cotton, F. J. Separation of the epiphysis of the olecranon, 692.

Coues, W. P. A case of ptomaine poisoning, 90.

Councilman, W. T. The course in pathology at the Harvard Medical School, 558, 567.

Diabetes. Notes on diabetes: (1) on the occasional low specific gravity of diabetic saccharine urine; (2) on casts in the urine during diabetic coma, Herrick, J. B., 543.

Digestive System. Appendicitis in a hernial sac, Tenney, B., 4, 12; a simple method for the quantitative analysis of the gastric contents for use in clinical work, Hewes, H. F., 9; a case of perforating gastric ulcer, operation, recovery, with remarks on the surgery of gastric ulcer, Lund, F. B., 25, 41; intestinal digestion, and its relation to pulmonary disease, Burr, C. B., 101; cases of cholecystotomy, Garceau, E., 104; intestinal obstruction, Beach, H. H. A., 110; a brief note on some of those grave abdominal lesions which often defy diagnosis, Manley, T. H., 135; diffuse peritonitis from acute appendicitis in a girl aged thirteen years, operation, recovery, Jenson, J. C., 163; perinephritic abscess involving the appendix, Willson, H., 222; the gastro-intestinal tract in tuberculous diseases, Pearce, *F.* S., 242; a method of determining the digestive power of gastric juice, as well as the absorptive power of the stomach, Austin, A. E., 246; idiopathic dilatation of the colon, Fitz, R. H., 274; intermittent gastric hypersecretion, with a report of a case, King, A. W., 293; strangulated diaphragmatic hernia, Mixter, S. J., 301; a case of acute general peritonitis, operation, recovery, Mumford, J. G., 301; a case of intestinal obstruction from a hair-ball, Brewster, G. W. W., 395; hair-eating children and convulsions, Lyon, F. D., 395; gunshot wound of the abdomen, with multiple wounds of the intestine, Lothrop, H. A., 405, 413; perigastric adhesions causing indigestion and gastric dilatation, Shattuck, F. C., 428; perforating gastric ulcer, operation, death, Warren, J. C., 428; perforating gastric ulcer simulating appendicitis, Shattuck, F. C., 429; hemorrhage from the whole gastric mucosa simulating gastric ulcer, Shattuck, F. C., 430; pyloric stenosis and gastric dilatation from gastric ulcer, hour-glass contraction of the stomach, Shattuck, F. C., 431; perforating ulcer of the duodenum, Weir, R. F., 453, 603; a study of the nature and significance of the symptoms in disorders of the stomach, Hewes, H. F., 701; the origin of oxaluria from fermentation in the gastro-intestinal tract, Herter, C. A., 545; acute phlegmonous gastritis, Kinnicutt, F. P., 545; cases of diarrhea associated with the presence of strongylus intestinalis in the stools, Thayer, W. S., 548; the attitude of the physician and surgeon to appendicular symptoms complicating typhoid fever, Hare, H. A., 550; observations on appendicitis, Van Gieson, I., 550; stomach conditions in early tuberculosis, Reed, B., 573; gastric hemorrhage, Rodman, W. L., 586, 604; perforating ulcer of the stomach, Finney, J. M. T., 604; malignant diseases of the stomach and pylorus, Mayo, W. J., 604; benign obstruction of the pylorus, Kammerer, F., 605; gastric dilatation, gastroptosis, Curtis, B. F., 605; hour-glass contraction of the stomach, Watson, F. S., 605; diagnosis of cancer of the stomach, Hemmeter, J. C., 606; adhesions of the stomach, Cabot, A. T., 606; gastric functions before and after gastro-enterostomy, Fischer, G. S., 606; stricture of the esophagus following typhoid fever, gastrostomy, Dennis, F. S., 606; surgery of the stomach, Keen, W. W., 607; the methods of closing abdominal incisions, Richardson, M.**

H., 607; strangulated hernia through a traumatic rupture of the diaphragm, laparotomy, recovery, Walker, E. W., 608; a retrospect of surgery of the stomach, Walker, H. O., 633; non-perforating gastric ulcer with and without hemorrhage, Rodman, W. L., 633; the diagnosis and treatment of cholelithiasis, Means, W. J., 633; cholecystotomy with special reference to removal of the mucous membrane of the gall-bladder in certain cases as a substitute, Mayo, W. J., 634; the importance of early operation for biliary calculi, Richardson, M. H., 634; the present status of the Murphy button, Murphy, J. B., 635; colostomy for permanent fecal fistula, Wyeth, J. A., 635; the treatment of obstinate constipation based on new points in the anatomy and histology of the rectum and colon, Pennington, J. R., 635; repair after resection of the intestine, Evans, W. A., 635; appendicitis, colitis as an etiologic factor, the question of removal of the appendix in all cases operated upon, Porter, M. S., 636; appendiceal fistula, Deaver, J. B., 636; dysentery, Flexner, S., 638; note on tropical dysentery, Musser, J. H., 638; foreign body in the rectum, Henry, J. G., 645; sarcoma of the intestines, Van Zwalenberg, C., 700.

Diphtheria. Varieties of the diphtheria bacillus, Westbrook, F. F., 548.

Dislocation. A case of old shoulder dislocation, Peckham, F. E., 192; unreduced and irreducible dislocations, Bevan, A. D., 698.

Dock, G. Address before the Section on the Practice of Medicine of the American Medical Association, 561.

Doolittle, W. F. Preliminary report on investigations in the bacteriology of scarlet fever in the scarlet-fever wards of the Children's Hospital, Berlin, 645.

Drugs. Sixteen years' experience in food and drug inspection, Abbott, S. W., 82.

Dudley, E. C. Stricture of the ureter a possible result of laceration of the cervix uteri, and ureterovaginal fistula a result of trachelorrhaphy, 215, 228.

Dunham, E. K. The nature of malignancy in neoplasms, 66.

Dust. Dust storms on Boston's Back Bay, 175; mud and dust in winter, 202; cases of pneumonia, 340.

Dwight, T. What position shall universities take with regard to investigation? 1.

Ends, B. B. Operations for injuries of the median and ulnar nerves, 700.

Ear. Otitis media in all grave diseases of infancy, Pomeroy, E. H., 59.

Earles, W. H. Injuries of the skull and its contents, 699.

Eastman, J. R. The advantages of retained catheter, 700.

Edes, R. T. A modification of the sphygmograph, 694.

Editorials. Our attitude toward investigation, 18; medical meetings and medical papers, 18; the case method of teaching medicine, 42; Sir James Paget, 43; the physician and the surgical consultant, 70; original research, a means or an end, 71; the dispersion of bequests, 94; the wounded in South Africa, 95; report of the Surgeon-General of the Army, 118; military surgery in South Africa, 118; the evolution of surgery in London, 147; sanitariums for tuberculosis, 149; human vivisection, 172; State care of the insane, 173; clinical instruction in small sections, 174; dust storms on Boston's Back Bay, 175; annual report of Harvard University, 201; mud and dust in winter, 202; cases of rash after enemata, 203; the limit is reached, 204; sanatoria for tuberculosis and prophylaxis, 230; some anti-vivisection "arguments," 231; the controversy as to the nutritive value of alcohol, 258; the volumes of "Proceedings," 259; progress in medical teaching, 282; Christian Science a menace to the public weal, 283; the question of prizes, 283; the development of out-patient departments, 310; our attitude toward epidemic disease, 311; the Craig Colony for Epileptics, 311; the proper seating of school children, 339; the Pathological Institute of the New York State Hospitals, 339; pneumonia, 340; mosquitoes and malaria, 340; destruction of the mosquito for the limitation of malaria, 341; The Long Island Hospital, Boston Harbor; report of the trustees, 362; on the effect of the exclusion of certain diseases as causes of mortality, 363; the "humane" bullet, 364; the responsibilities and qualifications of a health commissioner, 366; pharmacal translations, 366; swedish gymnastics, 390; science pure and science applied, 411; annual report of the Massachusetts General Hospital, 415; medicine as a means of grace, 438; the fatality of certain diseases, of a certain number attacked what percentage dies? 439; lobar pneumonia, 440; small-pox is a preventable disease, 440; typhoid fever and the water supply of Paris, 468; Sir Thomas Douglas Maclagan, 496; Dr. Bowditch's address, 468; hospital endowment and hospital abuse, 522; the filtering power of the soil and the conveyance of bacteria by means of subsoil water, 523; first report of the Massachusetts State Board of Insanity, 551; the transmission of syphilis to the lower animals, 552; compulsory notification of tuberculosis, 573; proprietary nomenclature of the pharmacopeia, 576; the twenty-fourth annual report of the Local Government Board of England (1898-99), supplement. Report of the medical officer, 609; hospital statistics, 611; the Massachusetts Medical Society, 641; the death-rate of Chicago, 642; American Medical Association, 642; three notable volumes, 671; alcohol in the tropics, 672; adjustable school furniture, 673; the scientific physician, 701; adjustable furniture for schools, 702.

Education. The case method of teaching systematic medicine, Cannon, W. B., 31; the case method of teaching medicine, 42; the case method of teaching systematic medicine, White, J. W., 153; a system of clinical instruction, for the simultaneous instruction in small sections of a large number of students, Wentworth, A. H., 155; clinical instruction in small sections, 174; annual report of Harvard University, 201; progress in medical teaching, 282; the old order changes, Mumford, J. G., 586; vivisection in the Harvard Medical School, a reply, Putnam, J. J., 209; the medical school of the future, Bowditch, H. P., 445; some thoughts on medical education, Shattuck, F. C., 529; the inductive method applied to medicine, Eliot, C. W., 557, 567; the course in pathology at the Harvard Medical School, Councilman, W. T., 558, 567; the case system in medicine, Cannon, W. B., 563, 568; a personal experience in the teaching of surgery, Burrell, H. L., 565, 568; a consideration of the principal objections to "section teaching," together with some of its advantages, Wentworth, A. H., 566, 568; on medical education, Wyman, M., 569; the endowment of medical colleges, Keen, W. W., 583.

Egan, P. R. The best diet for the tropics, the army ration, 47.

Elkhorn, M. The early recognition and management of malignant disease in the digestive system, 67.

Electrozone. Disinfectant value of "electrozone," 394.

Eliot, C. W. The inductive method applied to medicine, 557, 567.

Elting, A. W. Intermittent gastric hypersecretion, with a report of a case, 293.

Engelmann, G. J. Third International Congress of Obstetrics and Gynecology, held at Amsterdam, August 8-12, 1899, 403, 412.

Epidemic Disease. Our attitude toward epidemic disease, 311.

Epilepsy. Epilepsy, Paul, W. E., 107, 112; the Craig Colony for Epileptics, 311; a communication on the relation of uric-acid secretion to epileptic attacks, Putnam, J. J., and Pfaff, F., 543.

Epistaxis, Cobb, F. C., 2, 12.

Ernst, H. C. Development of the microscope, 395; closing statement for the remonstrants to the Massachusetts House bill No. 917, entitled "an act for the further prevention of cruelty to animals," before the joint committee on probate and insolvency, March 15, 1900, 650.

Evans, W. A. Repair after resection of the intestine, 635.

Extra-uterine Pregnancy. A case of extra-uterine pregnancy, with operation, Johnson, F. W., 355; double extra-uterine pregnancy, Cabot, R. C., 428; a case of extra-uterine pregnancy, Holyoke, F., 655.

Fatality of certain diseases: of a certain number attacked what percentage dies? 439.

Fibroids. The conservative operative treatment of fibroids, report of three cases, Burrage, W. L., 349, 358; two cases illustrating conservative operations for uterine fibroids, Kingman, R. A., 352.

Filaria. A case of filaria, with specimens of the adult parasite, Lothrop and Pratt, 548.

Finney, J. M. T. Perforating ulcer of the stomach, 604.

Fischer, C. S. Gastric functions before and after gastro-enterostomy, 606.

Fitz, G. W. Swedish gymnastics, 579.

Fitz, R. H. Idiopathic dilatation of the colon, 274; case of cystoma of the pancreas, 550.

Flexner, S. The nature of the new tissue in cirrhosis of the liver, and its distribution, 549; dysentery, 638.

Folie à deux, Jelly, A. C., 369, 386.

Food. Sixteen years' experience in food and drug inspection, Abbott, S. W., 82; aseptic milk, Randall, G. M., 122.

Fractures. The open or operative treatment of fresh fractures, is it ever justifiable? Scudder, C. L., 289, 304, 322.

Freeman, L. Union following pathological fracture of the femur due to secondary carcinoma, spontaneous disappearance of carcinoma of the lip, 696.

Frontal Sinus. Empyema of frontal sinus, Paige, J. D., 355.

Fungus. A new pathogenic fungus (sporothrix Schenck), Hektoen, L., 545.

Fussell, M. H. Perichondritis of the larynx in typhoid fever, with exhibition of a patient and a specimen, 550; examination of the blood, its value to the general practitioner, 634.

Galloway, H. P. H. The relation of deformity of the pelvis to lateral curvature of the spine, 629.

Garceau, E. Cases of cholecystotomy, 104.

Generative System. Recent progress in genito-urinary surgery, Watson, F. S., and Thorndike, F., 63; malignancy in the female genito-urinary system, Baldwin, L. G., 66; on the high operation for disease within the scrotum, Mumford, J. G., 89; ovarian cysts with twisted pedicles, Richardson, M. H., 91; stricture of the ureter a possible result of laceration of the cervix uteri and ureterovaginal fistula a result of trachelorrhaphy, Dudley, E. C., 215, 228; abstract of paper on "further experience with the operative treatment of," Burrage, W. L., 241, 255; steps in the treatment of chronic hyperplastic and senile endometritis, putrid abortion and puerperal sepsis, Johnson, F. W., 269, 279; cysts of both ovaries, hydatidiform mole, removed by abdominal incision, Porter, C. B., 298; ruptured ovarian cyst, Cleveland, C., 337; the conservative operative treatment of fibroids, report of three cases, Burrage, W. L., 349, 358; vaginal myomectomy, removal of fibroid nodule three centimetres (one and one-fourth inches) by one and one-half centimetres (seven-eighths inch) of subperitoneal evolution from the front wall of the uterus by anterior colpotomy, Burrage, W. L., 349; morcellation of submucous nodule at fundus, and polyp with pedicle springing from fundus, Burrage, W. L., 350; two cases illustrating conservative operations for uterine fibroids, Kingman, R. A., 352; a peculiar case of adenocarcinoma of the body of the uterus, Vietor, A. C., 353; on intermenstrual dysmenorrhea, Storer, M., 397, 411; treatment of cancer of cervix of the uterus compliheated, Johnston, G. B., 401, 411; Third International Congress of Obstetrics and Gynecology, Engelmann, G. J., 403; the question of supernumerary Fallopian tubes, with specimens of Fallopian tubes with supernumerary ostia, Vietor, A. C., 513, 518; a new method of intra-abdominal operation for retroverted uteri, Kaan, G. W., 602.

Gibson, W. P. The simple and efficient treatment of calcaneus paralyticus in young children, 629; a case of tuberculosis of the astragalus with anchylosis and subsequent amputation, 631.

Gillette, A. J. Spasmodic lateral curvature of the spine, 629.

Lovett, R. W., and Withington, C. F. Typhoid spine, 317, 336.
Lund, F. B. A case of perforating gastric ulcer, operation, recovery, with remarks on the surgery of gastric ulcer, 25.
Macdonald. Address before the Medical Society of the State of New York, 166.
MacDougall, R. Psychology and heredity, 185, 197, 219.
Maceo. Antonio Maceo's skull, 207.
Maine. Special medicine chest for the hospital ship *Maine*, 21.
Malaria. Anopheles and malaria, Celli, 261; mosquitoes and malaria, 340; destruction of the mosquito for the limitation of malaria, 341; malaria and mosquitoes, Rosse, I. C., 628; pathology of malarial fevers, structure of the parasites and changes in the tissues, Lazear, J. W., 640; etiology of malaria with special reference to mosquitoes, Sternberg, W. S., 641, some typical cases of estivo-autumnal and tertian malarial fevers, with study of the parasites observed in the blood, Craig, C. F., 668; clinical observations in malaria, Jones, F. A., 668; malarial hemoglobinuria, Burns, W. B., 668; prolonged fevers of obscure origin, Preble, R. B., 668.
Malignant Disease, Bryant, J. D., 65; the nature of malignancy in uterine disease, Kelly, H. A., 66; malignancy in the female genito-urinary system, Baldwin, L. G., 66; malignant disease of the nose and throat, Wright, J., 67; the early recognition and management of malignant disease in the digestive system, Einhorn, M., 67; the treatment of inoperable malignant tumors, Coley, W. B., 68.
Mallory, F. B. Proliferation and phagocytosis, 547.
Manley, T. H. A brief note on some of those grave abdominal lesions which often defy diagnosis, 135.
Marcy, H. O. Cure of inguinal hernia in the male, 665.
Marine-Hospital Service. Examination for assistant surgeons in the United States Marine-Hospital Service, 74.
Massachusetts General Hospital. Clinical meeting of the medical board, 274, 297, 425; annual report, 415.
Materia Medica and Therapeutics. A clinical study of heroin, Daly, J. R. L., 190; disinfectant value of electrozone, 394; the hydriatic treatment of tuberculosis, Kellogg, J. H., 574; petroleum oil in the treatment of phthisis, Robinson, W. D., 574; proprietary medicines and the pharmacopeia, 576; a final report on the use of pure carbolic acid in the treatment of tubercular and purulent diseases of joints and bones, Phelps, A. M., 629.
Mayo, W. J. Malignant diseases of the stomach and pylorus, 604; cholecystotomy, with special reference to removal of the mucous membrane of the gall-bladder in certain cases as a substitute, 634.
McCurdy, S. L. Developmental shortening in tubercular bone disease, 664.
Means, W. J. The diagnosis and treatment of cholelithiasis, 633.
Measles. The importance of restricting measles, 314.
Medicine as a means of grace, 438.
Meetings. Medical meetings and medical papers, 18.
Microscope. Development of the microscope, Ernst, H. C., 395.
Milk. Aseptic milk, Randall, G. M., 122.
Mind. State control of the insane, 74; report of a few cases of insanity treated by the cold pack, Abbott, 164; State care of the insane, 173; the unity of the acute psychoses, Knapp, P. C., 181; psychology and heredity, MacDougall, R., 185, 197, 219; Folie à deux, Jelly, A. C., 369, 386; the problem of Boston's insane, Knapp, P. C., 377, 383; the work of the trustees of the Boston Insane Hospital and their plans for its future development, Baldwin, H. C., 379, 383; first report of the Massachusetts State Board of Insanity, 551.

Mitchell, J. K. Study of a mummy with infantile paralysis, 550.
Mixter, S. J. Strangulated diaphragmatic hernia, 301.
Monks, G. H. A new needle holder, 296.
Myers, J. L. Three unusual cases of angioneurotic edema in infancy, 10; splenic anemia, 422, 436.
Mortality. On the effect of the exclusion of certain diseases as causes of mortality, 363.
Mosquitoes and malaria, 340; destruction of the mosquito for the limitation of malaria, 341; mosquitoes and the march of empire, 419; malaria and mosquitoes, Rosse, I. C., 623; etiology of malaria, with special reference to mosquitoes, Thayer, W. S., 641; structural and other differences between the several mosquitoes of North America, Howard, L. O., 641.
Mumford, J. G. On the high operation for disease within the scrotum, 89; the old order changes, 286, 315; a case of acute general peritonitis, operation, recovery, 301; a case of Chopart's amputation, with tendon implantation and tenotomy, 301.
Munson, E. L. The ideal ration for an army in the tropics, 463, 489, 501, 534.
Murphy, J. B. The present status of the Murphy button, 635.
Musser, J. H. Note on tropical dysentery, 626.
Nelson, C. D. Experiments with tuberculin, 676.
Nervous System. On the treatment of pain in tabes dorsalis, report of a case, Lindström, A. H., 37; epilepsy, Paul, W. E., 107, 112; case of combined superior and inferior poliencephalitis, Walton, G. L., 169; a case of multiple cerebral hemorrhages from chronic lead poisoning, with necropsy, Courtney, J. W., 136, 142; the unity of the acute psychoses, Knapp, P. C., 181; the gastro-intestinal tract in nervous disease, Pearce, F. S., 242; two cases of Thompsen's disease, and one of transient myotone, occurring in one family, Lord, S. A., 349; injuries about the shoulder at birth, Stone, J. S., 265; instruction in co-ordination in tabes, Putnam, J. J., 274; muscular dystrophy, Putnam, J. J., 274; case of acromegaly, Walton, G. L., 274; a case of poliencephalitis superior and inferior with acute anterior poliomyelitis, Taylor, E. W., 275; the Craig Colony for Epileptics, 311; hydrophobia in Athens, 314; a case of periodic palsy, with suggestions as to the pathogenesis, Putnam, J. J., 334; on distortion of the spine, with the report of two cases of diplegia brachialis dua of Erb's type, Courtney, J. W., 345; subcortical motor aphasia, Walton, G. L., 425; on ischemic paralysis and contracture of muscles, Bernays, A. C., 589; a communication on the relation of uric-acid secretion to epileptic attacks, Putnam, J. J., and Pfaff, F., 543; report of a case of acute ascending paralysis showing hematoporphyrinuria, Stoekton, C. G., 543; study of a mummy affected with infantile paralysis, Mitchell, J. K., 550; tetanus treated with antitetanic serum, Blake, J. D., 609; laminectomy for diseases and injuries to the spinal cord, Lloyd, S., 699; operations for injuries of the median and ulnar nerves, Eads, B. S., 700.
Newton, R. C. Report of certain cases of tuberculosis which were apparently due to the nature of the soil, 571.
Noble, C. P. Remarks on the influence of technique upon the results of closure of wounds of the abdominal walls, 237, 256.
Nomenclature. The limit is reached, 204.
Nose. Malignant disease of the nose and throat, Wright, J., 67.
Obesity. DeBlois, 335.
Ochsner, A. J. The treatment of hernia in children, 665.
Old Age. Results of surgery in the aged, Tuttle, J. P., 700.
Olecranon. Ununited fracture of olecranon, Porter, C. B., 299; separation of the epiphysis of the olecranon, Cotton, F. J., 692.
Orthopedic Surgery. Report on orthopedic surgery, Bradford, E. H., and Brackett, E. G., 225.
Orthopraxy. The simple and efficient treatment of calcaneus paralyticus in young children, Gibney, V. P., 629; a final report on the use of pure carbolic acid in the treatment of tubercular and purulent diseases of joints and bones, Phelps, A. M., 629; the mechanics of lateral curvature of the spine, Lovett, R. W., 629, 639; some of the problems involved in the treatment of lateral curvature of the spine, Shaffer, N. M., 629; the relation of deformity of the pelvis to lateral curvature of the spine, Galloway, H. P. H., 629; spasmodic lateral curvature of the spine, Gillette, A. J., 629; the results of my observations in lateral curvature of the spine, clinically, mechanically and pathologically, Phelps, A. M., 629; the support supplementing the Taylor brace in Pott's disease, Packard, G. B., 630; a suspension pressure chair for scoliosis, Hoffmann, P., 630; results of treatment of congenital dislocation of the hip, Bradford, E. H., 630; a new back brace for Pott's disease, Dane, J., 630; tendon transplantation in the treatment of paralytic deformities, Townsend, W. R., 630; a case of congenital dislocation of the shoulder, with radiograph, Porter, J. L., 630; a case of tuberculosis of the astragalus with anchylosis and subsequent amputation, Gibney, V. P., 631; forcible correction of spinal curvature followed by paralysis, Taylor, R. T., 662; a case of scorbutic spine, Ridlon, J., 662; knee-joint surgery for other than tubercular processes, Goldthwait, J. E., 662; the treatment of vertebral tuberculosis with reference to the forcible correction of the deformity, Ridlon, J., 663; brace for lateral curvature of the spine, Davis, G. G., 664; retardation of growth as a cause of shortening after coxitis, Taylor, H. L., 664; developmental shortening in tubercular bone disease, McCurdy, R. L., 665; rapid osteoclasis for the correction of rhachitic deformities of the legs, Blanchard, W., 664; an operation for ununited intracapsular fracture of the hip, Davis, G. G., 664.
Osler, W. A Rhode Island philosopher, Elisha Bartlett, 49, 77.
Out-Patient Department. The development of out-patient departments, 310.
Ovary. Ovarian cysts with twisted pedicles, Richardson, M. H., 91; cysts of both ovaries, hydatidiform mole removed by abdominal incision, Porter, C. B., 298; ruptured ovarian cyst, Cleveland, 337.
Packard, G. B. Anterior support supplementing the Taylor brace in Pott's disease, 630.
Paige, J. D. Empyema of frontal sinus, 355.
Pancreas. Case of cystoma of the pancreas, Fitz, R. H., 550.
Papers. Medical meetings and medical papers, 18.
Parasites. A case of filaria, with specimens of the adult parasite, Lothrop and Pratt, 548.
Paris. Letter from Paris, 261; an excursion to the Paris exhibition, Crothers, T. D., 283; typhoid fever and the water supply of Paris, 466.
Park, W. H. The elimination of deleterious substances from antitoxic sera, 548.
Patella. Fresh fractured patella, sutured with catgut through the periosteum, Warren, J. C., 276; slipping patella, Porter, C. B., 298; fracture of right patella, Porter, C. B., 299; fractures of the patella, Barton, J. W., 698.
Pathology. Report on progress in pathology, Wright, J. H., 253; the Pathological Institute of the New York State Hospitals, 339; the course in pathology at the Harvard Medical School, Councilman, W. T., 537, 568.
Paul, W. E. Epilepsy, 107, 112.
Pavements. Street paving in Boston, 234; street pavements, 263.
Pearce, F. S. The gastro-intestinal tract in nervous disease, 242.
Peckham, F. E. A case of old shoulder dislocation, 192.
Pelvic Gumma, Stone, A. K., 425.
Pelvis. Congenital cystic tumor of the pelvis, Willard, De F., 698.
Pennington, J. B. The treatment of obstinate constipation based on new points in the anatomy and histology of the rectum and colon, 635.
Pharmacopeia. H. C. Wood, address, 487.
Phelps, A. M. A final report on the use of pure carbolic acid in the treatment of tubercular and purulent diseases of joints and bones, 629; the results of my observations in lateral curvature of the spine, clinically, mechanically and pathologically, 629.
Physical training and Swedish gymnastics, 397.
Physiology. American Society of Physiologists, 21.
Plague. Precautions against the importation of plague, 121; a plague laboratory, 207; plague at Mengtze, Yunnan, China, 288; reports of plague in California exaggerated, 579.
Poisons. A case of ptomaine poisoning, Cones, W. P., 90; a case of multiple cerebral hemorrhages from chronic lead poisoning, with necropsy, Courtney, J. W., 136, 142.
Pomeroy, S. H. Otitis media in all grave diseases of infancy, 89.
Porter, C. A. Traumatic rupture of echinococcus cyst of liver, 302.
Porter, C. B. Sarcoma of the tonsil, 297; slipping patella, 298; cysts of both ovaries, hydatidiform mole, removed by abdominal incision, 298; dislocation of internal semilunar cartilage, removal, good recovery, 298; ununited fracture of olecranon, 299; floating cartilage of the knee joint, 299; fracture of right patella, 299; comminuted fracture of humerus, 300; fracture of surgical neck of humerus, with displacement of head of humerus, 300.
Porter, J. L. A case of congenital dislocation of the shoulder, with radiograph, 630.
Porter, M. B. Appendicitis, colitis as an etiologic factor, the question of removal of the appendix in all cases operated upon, 626.
Pratt, J. H., and Fulton, F. T. Report of cases in which the bacillus aërogenes capsulatus was found, 599.
Preble, R. B. Prolonged fevers of obscure origin, 668.
Pregnancy, affections connected with. A sterilizer and equipment for obstetric cases, Higgins, F. A., 85, 91; recent progress in obstetrics, Higgins, F. A., 136; steam in the treatment of chronic, hyperplastic and senile endometritis, putrid abortion and puerperal sepsis, Johnson, F. W., 269, 279; a case of extra-uterine pregnancy with operation, Johnson, F. W., 335; treatment of cancer of the cervix of the uterus complicated by pregnancy, Johnson, G. B., 401, 411; Third Clinical International Congress of Obstetrics and Gynecology, Engelmann, G. J., 403; double extra-uterine pregnancy, Cabot, H. C., 423; a case of pernicious vomiting of pregnancy, Twombly, E. L., 510; bicornate uterus, with twin pregnancy, abortion from one horn, Winn, C. H., 511; a case of pernicious vomiting of pregnancy, Knight, H. S., 512; a case of extra-uterine pregnancy, Holyoke, F., 535.
Prizes. The question of prizes, 283.
Proceedings. Two volumes of "Proceedings," 259.
Proliferation and phagocytosis, Mallory, F. B., 547.
Pryor, W. R. A cystocope, 357.
Psychology and Heredity, MacDougall, R., 185, 197, 219.
Ptomaines. A case of ptomaine poisoning, Cones, W. P., 90.
Putnam, J. J. Vivisection in Harvard Medical School, a reply, 209; instruction in co-ordination in tabes, 274; muscular dystrophy, 274; a case of periodic palsy, with suggestions as to the pathogenesis, 334.
Putnam, J. J., and Pfaff, F. A communication on the relation of uric-acid secretion to epileptic attacks, 543.
Quarantine. Additions to quarantine regulations, 177.
Randall, G. M. Aseptic milk, 122.
Ration. The ideal ration for an army in the tropics, Munson, E. L., 463, 489, 501, 534.
Realism in medicine, Cabot, A. T., 615, 647.
Recent Progress. Genito-urinary surgery, Watson, F. S., and Thorndike, P., 63; obstetrics, Higgins, F. A., 136; dermatology, Bowen, J. T., 193; orthopedic surgery, Bradford, E. H., and Brackett, E. G., 225; pathology, Wright, J. H., 253; thoracic diseases, Sears, G. G., and Bartol, J. W., 276, 302; public hygiene, Abbott, S. W., 330, 356, 380, 432.
Reed, S. Stomach conditions in early tuberculosis, 573.
Relapsing Fever. A case of relapsing fever, Ward, G. O., 36.
Research. Original research: a means or an end, 71.
Respiratory System. Influenza in London, 75; intestinal digestion and its relation to pulmonary disease, Burr, C. R., 101; the Massachusetts State Hospital for Consumptives at Rutland, its purpose and the work accomplished during the first year, Bowditch, V. Y., 127, 142; recent progress in thoracic diseases, Sears, G. G., and Bartol, J. W., 276, 302; influenza and pneumonia in New York, 285; idiopathic pneumatosthorax, with recovery after aspiration, Boland, E. S., 321, 333; dust pneumonia, 340; lobar pneumonia, 440; sanitarium treatment of pulmonary tuberculosis and its results, Trudeau, E. L., 544; degenerated echinococcus cyst of the pleura, Cary, C., 550; report of certain cases of tuberculosis which were apparently due to the nature of the soil, Newton, R. C., 571; educational and legislative control of tuberculosis, Denison, C., 573; some phases of the tuberculosis problem in Colorado, Bonney, S. G., 572; the construction and management of small sanatoria for consumptives, Klebs, A. C., 572; some personal observations on the effect of intrapleural injections of nitrogen gas in tuberculosis, Loomis, H. P., 573; subsequent history of patients apparently cured by antituberele serum, Stubbert, J. E., 573; the phlebitis of advanced phthisis, with report of cases of phthisis following ab-

scesses of the hand, Curtin, R. C., 573; the diagnostic value of tuberculin in tuberculosis, Anders, J. M., 573; the hydriatic treatment of tuberculosis, Kellogg, J. H., 574; petroleum oil in the treatment of phthisis, Robinson, W. D., 574; stamina, the special benefit of fats of one kind or another as a necessary article of diet to fortify the system against tubercle bacilli, Bell, A. N., 574; serum therapy in croupous pneumonia, Wilson, J. C., 630; external drainage of superficial lung cavities, with report of two successful cases, Wills, W. L., 665.

Rheumatism. Pathology of rheumatism, Rieman, D., 669; rheumatism and the prevention of heart complications, Walsh, J. J., 669; the relations of chorea and rheumatism, Burr, C. W., 669; heart in rheumatism, Rochester, Del., 669; pathogenesis and features of arthritis deformans, Kelly, A. O. J., 669.

Richardson, M. H. Ovarian cysts with twisted pedicles, 91; the case of a man who swallowed his suspenders, removal by external esophagotomy, recovery, other similar cases, 158; the methods of closing abdominal incisions, 607; the importance of early operation for biliary calculi, 634.

Ridlon, J. A case of scorbutic spine, 662; the treatment of vertebral tuberculosis with reference to the forcible correction of the deformity, 663.

Rieaman, D. Pathology of rheumatism, 669.

Robinson, W. D. Petroleum oil in the treatment of phthisis, 574.

Rochester, DeL. Heart in rheumatism, 669.

Rodman, W. L. Gastric hemorrhage, 586, 604; non-perforating gastric ulcer, with and without hemorrhage, 635.

Roentgen. X-ray examinations of the abdomen, Williams, F. H., 93; the value of x-ray examinations in the less frequent diseases of the chest illustrated by their use in those cases where aneurism is present or suspected, Williams, F. H., 54, 81; note on x-ray examinations of the lung, Williams, F. H., 555; surgical errors of skiagraphy, Beck, C. G., 666; diagnosis of calculous disease of kidney, ureters and bladder by the x-rays, Leonard, C. L., 666.

Rosse, I. C. Malaria and mosquitoes, 628.

Sanatoria for tuberculosis and prophylaxis, 230.

Sanitariums for tuberculosis, 149; local sanitariums for tuberculosis in New York State, 150.

Scabies. The discovery of scabies, 122.

Scannell, D D. The clinical value of Oliver's hemocytometer, 160.

Scarlet Fever. Preliminary report on investigations in the bacteriology of scarlet fever in the scarlet-fever wards of the Children's Hospital, Berlin, Doolittle, W. F., 645.

School. The proper seating of school children, 339; adjustable school furniture, 673; adjustable furniture for schools, 702.

Science pure and science applied, 414.

Scrotum. On the high operation for disease within the scrotum, Mumford, J. G., 89.

Scudder, C. L. The open or operative treatment of fresh fractures, is it ever justifiable? 289, 304; x-ray plates of traumatic separation of epiphysis, 300.

Sea. The influence of sea-air and sea-water on disease, Stewart, W. B., 639.

Sears, G. G., and Bartol, J. W. Report on progress in thoracic diseases, 276, 302.

Serum. The elimination of deleterious substances from antitoxic sera, Park, W. H., 548.

Sex. Determination of sex at will, 231.

Shaffer, N. M. Some of the problems involved in the treatment of lateral curvature of the spine, 629.

Shattuck, F. C. Adenocystoma of the liver, 427; perigastric adhesions causing indigestion and gastric dilatation, 428; perforating gastric ulcer simulating appendicitis, 429; hemorrhage from the whole gastric mucosa simulating gastric ulcer, 430; pyloric stenosis and gastric dilatation from gastric ulcer, hour-glass contraction of the stomach, typhoid fever, perforation, immediate operation, 432; some thoughts on medical education, 529.

Shattuck, G. B., Warren, J. C., and Cobb, F. A study of twenty-four cases of typhoid fever with symptoms of peritoneal infection, laparotomy, 677, 696.

Shoulder. A dislocation of the shoulder explaining the action of Kocher's method, Warren, J. C., 40; a case of old shoulder dislocation, Peckham, F. E., 192; injuries about the shoulder at birth, Stone, J. S., 265.

Skull. Growths in the frontal sinus, Hamilton, W. D., 699; injuries of the skull and its contents, Earles, W. H., 699.

Small-pox. Smallpox in a prevensible disease, 440; pseudo (?) or modified (?) small-pox, Happel, T. J., 640.

Smith, T. Adaptation of pathogenic bacteria to different species of animals, 473.

Smithwick, M. P. Nitrate of silver in hyperchlorhydria, 6, 15.

Societies. American Climatological Association, 571; American Medical Association, 621, 642, 665, 696; Orthopedic Association, 629, 662; American Society of Physiologists, 21; American Surgical Association, 603; Association of American Physicians, 542; Association of Military Surgeons, 613; Boston Medico-Psychological Society, 164, 197, 386; Boston Society for Medical Improvement, 11, 116, 197, 333, 435, 567, 696; International Congress of Obstetrics and Gynecology, 403; International Medical Congress, 177, 314; Massachusetts Medical Society, 641, 660, 675; Massachusetts Medico-Legal Society, 658; New York, Medical Society of the State of, 166; New York Obstetrical Society, 337; New York State Medical Association, 65; Obstetrical Society of Boston, 91, 228, 255, 411; Suffolk District Medical Society, 15, 40, 140, 279, 301, 334, 357, 412, 515.

Sociological status of the physician, Blake, C. J., 482.

Soil. The filtering power of the soil and the conveyance of bacteria by means of subsoil water, 523.

Solly, S. E. The blood changes in high altitudes, 574.

South Africa. War notes from South Africa, 47.

Spine. Typhoid spine, Lovett, R. W., and Withington, C. F., 317, 334; on distortion of the spine, with the report of two cases of diplegia brachialis due to this cause, Courtney, J. W., 345; the mechanics of lateral curvature of the spine, Lovett, R. W., 622, 629; some of the problems involved in the treatment of lateral curvature of the spine, Shaffer, N. M., 629; the relation of deformity of the pelvis to lateral curvature of the spine, Galloway, H. P. H., 629; spasmodic lateral curvature of the spine, Gillette, A. J., 629; the results of my observations in lateral curvature of the spine, clinically, mechanically and pathologically, Phelps, A. M., 629; anterior support supplementing the Taylor brace in Pott's disease, Packard, G. H., 630; a suspension pressure chair for scoliosis, Hoffmann, P., 630.

Spleen. Splenic pseudoleukemia, historical sketch, Cabot, R. C., 421, 435; splenic anemia, Morse, J. L., 422, 436; splenic anemia, Jackson, H., 423, 436; a case of splenic anemia, Jackson, J. M., 424.

Splints. A lecture on surgical splinting, Tracy, E. A., 206.

State Medicine. Oration on State medicine, Vaughan, V. C., 631; the law of dying declarations, Sughrue, M. J., 653, 658; a case of extra-uterine pregnancy, Holyoke, F., 655; the marks produced by pistol shots, Hough, G. de N., 657, 659.

Steam in the treatment of chronic hyperplastic and senile endometritis, putrid abortion and puerperal sepsis, Johnson, F. W., 269, 279.

Stengel, A. Aneurism of the aorta with rupture into the superior vena cava recognized during life, 556.

Sterilizer and equipment for confinement cases, Higgins, F. A., 98, 91.

Stewart, W. B. The influence of sea-air and sea-water on disease, 639.

Stimson, J. C. Diffuse peritonitis from acute appendicitis in a girl thirteen years old, operation, recovery, 163.

Stockton, C. G. Report of a case of acute ascending paralysis, without hematoporphyrinuria, 543.

Stone, A. E. Pelvic gumma, 425.

Stone, J. S. Injuries about the shoulder at birth, 265.

Address.

WHAT POSITION SHALL UNIVERSITIES TAKE WITH REGARD TO INVESTIGATION?[1]

BY THOMAS DWIGHT, M.D., LL.D., BOSTON,
Professor of Anatomy in Harvard Medical School.

When the honor was done me of asking me to take part in this discussion, my first thought, after the sensation of complacency at the compliment, was that there could hardly be a *discussion* where all held probably very nearly the same views, and that the great difficulty would be to say anything that would not be better said by another. Then as I began to think more carefully, I saw that the question was not, as I had at first imagined it to be, "What shall universities do to encourage those on their staffs to investigate?" It is far wider than that. It comprises a whole group of questions concerning which there may be every shade of opinion. So the more I thought, the more I admired the wisdom the committee had shown in their choice of a subject. Later still, it dawned upon me that surely it is a most satisfactory sign of progress that this Society should meet to discuss such a subject, with the conviction that, though without the shadow of a legal right to make claims, we are, nevertheless, sure of a sympathetic hearing from both universities and the public. First of all let us consider the place of investigation in education as a means of mental training, quite apart from any definite results. Surely this alone opens a wide field for one afternoon's ramble, in which there are diverging and recrossing paths enough to furnish us the surprises of unexpected partings and unhoped-for reunions.

I would here remark that perhaps some confusion is possible from different interpretations of the word, "investigation." According to some, it means simply practical work, object teaching, or, better still, object study. According to others, it is the search for something new. With regard to the value of the former we are all pretty well agreed. We do not need to be told what an advance it is over the old way of learning the statements of others concerning matters well within the sphere of observation. It may sometimes be carried too far; but in view of its great usefulness, we will not quarrel with a little abuse. With what is meant by the second interpretation the case is different. Excepting some singularly gifted natures, it does not, in my opinion, concern the student. The universal or even very general application of this method is the result of an extreme reaction. It rests on a fallacy. Because investigation is a good thing, and worthy of encouragement, which all must admit, it is assumed to be good for all, and an accepted method of education, which conclusion I cannot adopt. It is for the beginner to learn what is worth learning in his particular field first of all. It is not easy in these days to learn all that is worth learning even in a very restricted department. To start on investigation with this only half learned is a direct injury to the student, whom it turns to premature specialization. It is both foolish and cruel to exact investigation as a part of the regular training of every student, and very unjust to imply that those whose taste does not lie that way are mentally inferior to those who dabble in research, no matter how ineffectively. It may be replied that, granting this, still it is a good and necessary training for those who in after life are to become investigators. I incline to dissent still; for the born investigator (and no other is worth much trouble) no more needs encouragement to investigate than the fish does to swim. I would, if anything, restrain him till his education has become broad and his mind mature. He will very quickly more than make up the lost time. Then let him have every encouragement.

As regards education I speak as a professor in a medical school, whose career has been so placed that he has seen this school develop into a department of a university. I feel that, in common with others, it has reached a point when it is in danger from the side of its scientific friends who mistake or will not learn the true purpose of a medical school. I so rarely find myself in complete accord with Huxley that I cannot forbear, though it is not for the first time, quoting his deliberate opinion that whoever adds one tittle that is unnecessary to medical education is guilty of a very grave offence. If this be true, as I firmly believe it is, we must look to it that the candidate for the degree of M.D. be not robbed of his time, none too long for learning medicine as an art, by specially conducted excursions into abstract science. It may be said, and said truly, that without such auxiliaries the education of the student wants something of the breadth which his should have who aspires to stand on the pinnacle, but this only emphasizes the fact, now becoming daily clearer, that there has grown up the need of what may be called advanced medicine. Some would have this strictly post-graduate, but it is probably wiser to have a difference in the course. On the one hand, there is the young man who aspires to be a conscientious, everyday practitioner of medicine, looking forward to a life of hard work among suffering humanity. Such a one is not to be refused the degree of an honored university, and told superciliously to go to the little school round the corner. Neither is he who, looking at the matter more as a scholar, desires through his studies to train himself to teach others and to widen the horizon of knowledge, to be told that we have no help to offer to one of his ideals. We must provide for both, but with what power I have I shall always protest against sacrificing the first to the second, though the latter is the one with whom my tastes incline me to sympathize.

To sum up thus far, I conclude that it is not the duty of universities to urge, still less to force, original investigation upon students. It should be at hand for those whose zeal is so great that it will take no denial.

The next question is what universities should do for research in the community at large. Are more prizes and scholarships to be offered? As to prizes I should hesitate to say yes. It is not well that they should be too common; but of scholarships for deserving men we can hardly have too many. It is most desirable that the universities should award them. They cannot, indeed, give the funds, but these being provided, committees from the universities should give their time, care and experience to their proper administration. This is a most beneficent and dignified attitude for a university, midway between the generous donor and the deserving student, to see that the generosity of the former is neither neglected nor abused.

[1] Address opening the discussion at the Annual Meeting of the American Society of Naturalists and Affiliated Societies, December 29, 1899.

The next, and last, aspect of the question that I shall consider is, What shall a university do for the support and encouragement of investigators within its walls? The primary function, in my opinion, of a professor is to teach; but with certain exceptions of rare merit, it is necessary for his reputation and influence that he should do original work. The first duty of the university to him is that he should not be overburdened with teaching. The next problem is, how the expenses of his work are to be met. These must vary with the department. For some lines of research distant expeditions are requisite, necessarily so costly that they can hardly be provided for otherwise than by national or private munificence. But putting these aside, and speaking more particularly of biological and morphological work, the problem reduces itself to this: what help shall the university give to the investigator, (1) in the matter of providing the material, namely, the subject matter for the study; (2) the machinery and reagents for the work; (3) the means of illustrating it, and finally, of publishing the paper. The last need is not urgent on account of the great number of journals of all kinds, but it exists in isolated cases. Till comparatively recently the position of universities has been much like that of the Pickwick Club, which when sending its honored founder and his companions on their travels saw no objection to every member paying his own bills. But professors for the most part suffer from "that perpetual lack of pence which vexes public men," and those who are not yet professors are, of course, vexed the more. Is it fair that a serious tax ever increasing in direct ratio to his merit should be laid on the investigator, especially as the university profits in no small degree by his success? I am sure we shall all agree it is not. But then difficulties present themselves as to how this help is to be given and distributed, assuming that the university admits the claim. Who are to be the chief beneficiaries? The most distinguished or the most needy? The oldest because of his years? Or the youngest because of his youth? And again, is it just that the university should furnish large sums for bringing out papers of unknown merit? It seems to me that the most feasible way, if the money can be procured, is to place a sum in the hands of the professor at the head of each scientific department, to be spent for the good of that department, including publication, according to his discretion, or his lack of it. Should the latter be painfully apparent, the resulting unpopularity will surely be irresistible, and thus there will be a check on a system which may at first seem too arbitrary.

EPISTAXIS.[1]

BY FREDERIC C. COBB, M.D., BOSTON.

THE subject of this paper is too much within the experience of all physicians to allow me to hope that I can present many points of novelty and interest not already known to you all. Yet the causes and treatment of this affection are not uniformly considered by the general practitioner and specialist, and each may learn from the other in his treatment of the disease.

[1] Read at a meeting of the Boston Society for Medical Improvement, November 6, 1899.

Bleeding from the nose, to quote from Thomas Watson, may be a warning, a remedy, or a disease. The first two statements, that it is a warning and a remedy, used, I think, to be the idea of the older practitioners, when blood letting, either natural or artificial, was regarded as a panacea for all things. The last part of Watson's statement, that it is a disease, has obtained much more of late years, and is a natural reaction against the earlier practice of blood letting already spoken of. It should in reality be called a symptom, it seems to me, either of some local lesion in the nose, or of some general disease elsewhere. It may be said that cases of nose-bleed are sometimes idiopathic, but as our knowledge of pathology grows, we find fewer instances of idiopathic and more of causative elements previously overlooked.

The causes of nose-bleed may be divided into local and general. Perhaps the commonest local cause of epistaxis is deformity of the nasal septum. The mechanism of the bleeding in such cases is simple. A sharp anterior deviation of the nasal cartilage throws it broadside to the air current, and particles of dust and grit lodge upon the delicate mucous membrane, causing it to become inflamed and covered with a coating of crusts and scabs. These soon become such an annoyance to the patient that he scratches the surface with his finger nail or handkerchief in order to rid himself of the discomfort, thus causing a small ulceration which reaches some time later a blood-vessel and hemorrhage results.

Examination of the nostril shows the vessels on the anterior part of the septum dilated, and if the bleeding point be found, it is within reach of the finger nail of the patient's hand. Ulceration may, however, occur without the use of the finger nail where the surface of the septum is sufficiently inflamed. Epistaxis may occur further back on the septum, but this is more uncommon, and is, it seems to me, more apt to be a symptom of some graver disease. Of the more important local lesions causing epistaxis, fracture is perhaps the most common, and this may occur at the junction of the septum and cartilage, or from the driving in of the nasal bones. Fracture or dislocation of the cartilage is the common cause of bleeding in boxing. Of all lesions the new growths of the nose cause the most severe hemorrhage, especially the angiomata and angiosarcomata. Death has resulted from the former in cases reported by Panas and Richet, but fortunately such cases are rare. In my experience few non-malignant tumors cause bleeding except the angiomata, and even in the malignant growths, except those mentioned, hemorrhage of any severity is unusual. Foreign bodies in the nose seldom cause bleeding, although allowed to remain in the nostril for years. Of the constitutional diseases leading to epistaxis we have first plethora, a somewhat vague expression, and anemia. Epistaxis from plethora I have never seen, although it seems too well known to be doubted. Epistaxis from anemia must be very infrequent in the absence of any local lesions, and in both plethora and anemia one would require proof that no local lesion had existed. If we consider the hemorrhagic diathesis is it not fair to assume that some local break in continuity must exist, as it does in other parts of the body? This of course need be but slight in the nose, as, for instance, the local removal of crusts and scabs from the anterior nares. When we consider that it is only of late years that the nose has been carefully examined, we can easily suppose that slight nasal lesions have often been over-

looked in the report of cases. Curious cases of vicarious menstruation by bleeding from the nose, when the normal channels have been blocked, are recorded, but are of purely physiological interest. Venous hemorrhage from obstruction of the jugular, due to tight stocks or neckwear, are reported, but are to be taken with some reservation. Such stocks were worn by an enormous number of people at one time, and yet it is not claimed that any large number of persons suffered from epistaxis as a result.

Syphilis, phthisis and alchol are given by Browne as predisposing causes. The bleeding in phthisis is rather apt to take place in the posterior nares, and blood crusts seen there are often the only lesion to be found. Epistaxis in syphilis is not frequent, and I have only records of two cases, both from septal ulcerations and associated with necrosis. One of these had also periostitis of the nasal bones.

But there is one constitutional disease which, in my experience, at least, has been associated with epistaxis very frequently, and that is nephritis. This, although mentioned with many others by the books, I do not find emphasized as a common cause. Hemorrhage resulting from this cause is usually severe, since the disease affects the walls of the arteries. In order to put this point in a stronger light I will cite two cases:

Case I. C. D. September 26, 1896, had so severe a hemorrhage from the right nostril that the posterior nares were plugged by the family physician. Twenty-four hours later the plug was removed, but the bleeding at once recurred, and he was forced to replace the plug, which this time was allowed to remain in position for five days. On its removal the bleeding again recurred with as much violence as ever and it became necessary to resort to a third tampon to stop it. I saw the patient after the third tampon had been in position for forty-eight hours. Both anterior and posterior plugs were very foul and were carefully removed, and a ten-per-cent. solution of cocaine on absorbent cotton was placed in the anterior nares. After this had been allowed to remain in the nostril a few minutes it was withdrawn and the nostril carefully examined. A small projecting point on the septum was found and carefully cauterized with a crystal of chromic acid. No further hemorrhage occurred for two weeks, when on cleaning the nostril I accidentally loosened a scab caused by the chromic acid and a quite severe hemorrhage was the result.

This was promptly checked by a plug of cotton soaked in cocaine for a few minutes and a second cauterization, after which no bleeding occurred. As the bleeding point was well back on the septum out of reach of the finger, and as the hemorrhage was severe enough to be evidently arterial, I asked for an examination of the urine, which showed one-half per cent. albumin. Two years afterwards he died of nephritis. The bleeding had been the first sign by which attention had been called to the nephritis.

Case II. D. T., age fifty-four, came to me March 13, 1894, saying that he hawked blood from the posterior nares; lungs negative; no signs in nose or throat to account for hemorrhage. Examination of the urine showed considerable albumin. Nearly a year and a half later I heard that he was dying of Bright's disease.

Other such cases could be cited, but they only serve to show that the urine should be carefully examined in cases of severe nose-bleed. That milder cases may also be associated with the uric-acid diathesis I am sure, and I could cite examples where this has been the case. Enough has been said, however, to point out that cases of epistaxis should receive a good general examination, as well as a local one. The symptoms of epistaxis are too well known to be gone into at any length. Of course, where the origin is the anterior part of the septum, the bleeding is from the nostril corresponding to the lesion. When the bleeding occurs in the mouth the diagnosis of the locality of the lesion is not so evident. It is often a question, in such cases, whether the hemorrhage comes from the lungs or from the nasopharynx or nose. This question is often not easily settled and can only be decided by the presence of a bleeding point in the upper air tract. Sometimes a very sharp deviation in one nostril may determine the direction of the blood backward to the throat, instead of forward to the meatus.

The presence of bloody scabs and crusts in the nasopharynx is fairly good evidence of nasal bleeding, even if no blood has been thrown out of the nose. If there has been severe coughing or vomiting it is possible that the nasopharynx could have been filled with blood from below.

Prognosis. — Experience shows that epistaxis is liable to recur if the exciting cause is not eliminated, just as bleeding in any other locality repeats itself. Even if the vessel causing the trouble is blocked, others become diseased and break, with the same result. Where the bleeding is due to erosion of superficial vessels, caused by crusts and ulcerations of the cartilaginous septum, destruction of the larger vessels and removal of irritation caused by the scabs and crusts, and directions as to how to prevent their again forming, will prevent recurrence. In cases due to a more central disease, that disease should be treated.

Treatment. — The treatment of epistaxis varies much with the severity of the attack. Mild forms may be arrested by simple measures, such as ice to the side of the nose, cold to the spine, hot or cold water injections into the nares. After operations the patient is usually advised to try, in case of bleeding, ice-cold water injected into the nose. Most authors advise a preliminary trial of these simple measures before resorting to the more unpleasant ones. Hot mustard foot baths, ligation of the extremities, pressure of the facial artery, have also been recommended. Practically the most satisfactory procedure is to examine the septum with a strong light concentrated by a head mirror, and, if possible, ascertain the bleeding point on the septum.

The practical difficulties in the case are usually the great amount of blood and clots, which make the examination difficult. For this reason cocaine on pledgets of cotton should be introduced. The solution used should be from five to ten per cent., and should be left in from five to ten minutes. If this fails to stop the bleeding, suprarenal capsule may be used. Until about a year ago this latter agent was almost unknown. Its effect on the blood-vessels of the mucous membrane is almost magical, and it does not seem to injure the delicate lining of the nose in any way. This solution may be prepared from the tablets, or from powders, in about a ten-per-cent. solution. Its only disadvantage when used in operations is that subsequent bleeding may occur.

Pledgets of cotton soaked in a five- to ten-per-cent. cocaine solution should be first tried. These have two advantages — one of contracting the bleeding vessels in the mucous membrane, and the other that of increasing the lumen of the nostril for purposes of packing and making that process less painful.

If a bleeding point is found on the septum, it should be touched with a crystal of chromic acid fused on a probe, or by the galvanocautery heated to a dull-red heat. If this should fail, or a bleeding point cannot be found on account of the bleeding, suprarenal capsule, prepared as above described, in a ten-per-cent. solution may be used, and the bleeding point again searched for. If both these remedies fail, packing must be resorted to, and a few words with regard to the manner of packing may not be amiss. The method of packing, as usually practised, has several disadvantages. This method consists in plugging the posterior nares with a sponge drawn up into the nasopharynx by a stout string, which has been passed in by means of a Bellocq's canula, or a catheter. The anterior nares are plugged for a half inch or so with cotton or gauze. This method depends for its success on rendering the pressure of the effused blood in the nose equal to the arterial pressure. It takes no account of the bleeding spot itself. Its disadvantages are the very great discomfort to the patient of the posterior plug, and the possibility of injury to the ears by its pressure on the Eustachian openings, and the introduction of germs through the packing, which soon becomes foul. It is unnecessary, at present, since with cocaine we can introduce antiseptic gauze in long narrow strips as far as the posterior nares, and beginning at the bottom by strip on strip until the nostril is well packed. The gauze should be introduced with a pair of long forceps, or a notched probe, the first piece being laid along the floor. The gauze should be passed in about three inches, the distance to the posterior nares being measured by a finger in the posterior nares, if necessary. The gauze should be all in one strip for purposes of removal afterwards. The Eustachian prominence is thus left free. The packing should be left in twenty-four to forty-eight hours, and it cannot be too strongly emphasized that it should be put in with great gentleness, and very carefully withdrawn. It will be found that after the gauze has been thoroughly moistened with nasal secretion it can be withdrawn with less danger of pulling off the clots formed by the blood, and thus renewing the bleeding.

To sum up briefly: The causes of bleeding from the nose may be local or general. The local causes are more apt to be ulcerations of the blood-vessels, resulting from scabs and crusts on the septum. These may be caused by irritation, as in deflected septum, by foreign bodies (although this is rare), by new growths, and especially by operations for sarcomata. The general causes are plethora and anemia, the hemorrhagic diathesis, acute febrile diseases, vicarious menstruation and disease of the kidneys, syphilis, phthisis and alcohol. It seems to the writer that the occurrence of severe bleeding should lead to an examination of the kidneys as a cause.

Treatment. — Cauterization of the bleeding point on the septum with chromic acid, or galvanocautery, after cocainization. Suprarenal extract to be tried, its only disadvantage being the possible renewal of the hemorrhage from the reaction of the blood-vessels. Plugging when resorted to should be done by strips of gauze introduced along the floor of the nose by means of long forceps, the Eustachian prominence not to be occluded. Packing should be left in twenty-four to forty-eight hours, and withdrawn with the utmost care.

APPENDICITIS IN A HERNIAL SAC.[1]

BY BENJAMIN TENNEY, M.D., BOSTON.

NOT very long ago I was called to see a patient of Dr. W. L. Watson's, in Lincoln, Mass. She was seventy-nine years old, not vigorous but wiry. The day before, she began to have severe pain in the right groin, some abdominal pain and nausea, accompanied by much general prostration. Her bowels had been more constipated than usual for several days, and she had been eating less. Her tongue was thinly coated, pulse but little more rapid than normal, temperature 101°, and she had attempted to vomit several times.

On examination we found a tender swelling in the right groin, half-way between the pubic and iliac spines and just below Poupart's ligament, about the size of a walnut. It was doughy to the touch, not very movable, and gave no impulse on cough. The skin was not reddened. Six years before, she noticed this "lump" after some extra exertion, but it had never troubled her beyond being occasionally rather tender to pressure. It was not in the least tympanitic, and the abdomen was nowhere tender except just above Poupart's ligament on this side. Thinking it probably an old omental hernia suddenly strangulated, gentle taxis was tried and quickly given up as causing intense pain and doing no good. A large poultice was applied and she was made as comfortable as possible. Next day the symptoms were all decidedly worse, the swelling larger, and she requested operation to get rid of the pain. Considering her age and great prostration I began with local anesthesia, using the stronger Schleich solution. There was much fat under the skin, and there was great difficulty in isolating anything at first, but finally a mass of fat was lifted out, the size of a small hen's egg, which was pretty solid and which had a strong cord-like structure as a pedicle leading down to the femoral ring. My first thought was of a prolapsed ovary with tube attached, but as my thumb penetrated a small cavity, and about a teaspoonful of pus, with characteristic odor, escaped with some small hard masses, I decided that I had an inflamed herniated appendix. It was tied and cut off close to the ring, to which it was tightly adherent. The pain caused by manipulating the pedicle was so intense that a few whiffs of ether were given. The wound was carefully washed out and sewed up with gauze drainage down to the stump, but there was a slight infection of the wound, doubtless from the rupture of the sac, which disappeared in a few days, and her recovery was uneventful otherwise. Three inches of appendix had been removed. The small, hard masses had the exact size and shape of raisin seeds, and with the story of a plum pudding a few days before, I thought I had a double rarity, but Dr. Mallory pronounced them fecal masses.

Hernia of the appendix alone is unusual, though hardly to be called rare. Two lists were published in

[1] Read at a meeting of the Boston Society for Medical Improvement, November 6, 1899.

1895, one of 98 cases by Bajardi, and one of 25 by McAdam Eccles. Since then, Van Hook, of Chicago, has reported one inguinal case, Good and Rose, of London, each one case of femoral hernia, and the writer's is the fourth reported. Not having access to the original paper of Bajardi, I do not know how many cases are included in both his list and Eccles's, but there cannot be many, as Eccles's cases are mostly from London hospital records and museum specimens.

Counting the above four cases with Eccles's 25, we have inguinal hernias, 12, femoral, 16. From Bajardi's table we have inguinal, 57; femoral, 40; obturator, one. The unusually large proportion of femoral hernias is doubtless due to the difference in the distensibility of the two rings. The femoral might admit an appendix and keep out cecum or other intestine, while the internal abdominal ring would more easily dilate and admit them. Were cases of hernia of appendix with other viscera included in these lists, the proportion would be very different.

As to the question of strangulation or inflammation of the herniated appendix, undoubtedly three of Eccles's cases and probably 17 of Bajardi's were simply strangulated, as they were reduced and replaced in the abdomen with complete recovery, but to-day I imagine the rest would be classed as inflamed. In fact, just how much the condition of strangulation, meaning shutting off the circulation, is a cause of the inflammation is a matter to be considered in appendicitis within the abdominal cavity. Certainly the solitary terminal artery supplying the distal end of the tube, particularly when the mesentery extends only half-way out, is liable to compression either by a twist or sharp bend in the tube, by a large concretion within the tube moving to a narrower part during some great exertion, by the swelling of the tissues themselves as a result of some injury or bacterial infection, or by some narrow opening like the femoral or internal or external abdominal rings. When this single artery is blocked, we have every condition required for pus formation: warmth, moisture, bacteria and feebly-nourished cells for them to grow on.

The crises in these herniated appendices present precisely the same symptoms as those seen early in appendicitis within the abdominal cavity, but the tenderness is so sharply localized that it cannot be overlooked. In many cases there is the sudden onset, the nausea or vomiting, the constipation or diarrhea, and the great prostration; but the vomiting is never so severe or persistent or fecal as in intestinal obstruction and the constipation is rarely complete. After pus formation the symptoms and conditions are like those of appendicitis inside the abdomen, only modified by the different anatomical conditions. In Hall's case after three days the hernial sac and most of the abdomen were found full of pus, and the appendix gangrenous and perforated within the sac. This occurred in eight cases. In one of Eccles's cases a bone splinter came out through a fistulous opening in the groin. Dr. Fitz's article mentions a case of Dr. A. T. Cabot's with a fistulous opening into the appendix in the groin. Van Hook's case was a cystic appendix, ruptured into the abdominal cavity during taxis. Dr. Monks's case was supposed to be a scrotal abscess. They have been diagnosed as suppurating glands, as omental hernias, as hernias of the ovary, and as new growths. In fact, the correct diagnosis has never but once been made before operation, and then a patient who had been cured of a supposed abscess of the testicle returned to the same clinic with a solid cord in his scrotum.

The length of time these appendices have been herniated with no special symptoms is also interesting as bearing on the question of tenderness of the normal appendix, but is not very easily found. Hall's case was seventeen years old, and the hernia had existed since childhood, with no truss worn or symptoms mentioned till the attack. Annandale's case existed twenty years, no truss worn, no symptoms mentioned. Monks's case was an infant with slowly growing tumor of two months. Rose's case had existed thirty-eight years, and had been accompanied by occasional vomiting and general dyspeptic symptoms, entirely relieved by operation. One of Eccles's cases had existed eleven years, and another eight months. The writer's case had been herniated six years, and was also accompanied by irregularity of the bowels, occasional attacks of indigestion and abdominal pain, all naturally referred to other causes, and all relieved since operation.

These appendices were all much more exposed to pressure than in the normal situation, and yet there is no record of constant tenderness. For some time I have made it a routine practice in examining patients to locate and palpate the appendix whenever possible, and have found what I thought to be appendix in some 60 cases. In only four of these was more tenderness than was shown to the same deep pressure on the other side. I do not believe that the normal appendix is ever more painful on pressure than any other part of the abdominal contents. But it is easily conceivable that a large concretion distending the tube, or a raw infected spot within the tube, or a kink or bend in the tube, might cause sufficient pressure on the nerve ends to produce tenderness and the lesser reflex symptoms of irritation of the mesenteric nerves. That there is a very active reflex of this sort is sufficiently proved by the grave symptoms which always follow strangulation of an omental hernia, and which cannot be accounted for in any other way.

Dr. Fitz in his original paper of 1886 remarked, after describing some cases where the appendix after death showed decided pathological changes, and where no severe abdominal symptoms had ever been recorded, "The severity of these lesions suggests the probability that apparently slight disturbances of digestion were overlooked. The diarrhea, constipation or abdominal pain, especially when occasionally recurrent, were regarded as characteristic of a feeble digestion."

More than that, I believe that the "acute indigestion," sometimes put down as the immediate cause of an attack of appendicitis, is often simply the first symptom of pressure on these sensitive nerve ends, and that with care the tenderness can be made out long before there is a tumor, and the case then be intelligently watched for interference at the opportune time. While, to-day, we are usually able to recognize a well-developed case, and do not often permit patients to recover or die with a wrong diagnosis, there are many who neither recover nor die, but live on uncomfortably, enduring some form of indigestion, never feeling perfectly well and with a constant danger ahead, who might be much more useful and pleasant members of society if the reflex symptoms and tenderness of an abnormal and irritating appendix were discovered and appreciated by their medical adviser.

NITRATE OF SILVER IN HYPERCHLORHYDRIA.[1]

BY M. P. SMITHWICK, M.D., BOSTON.

My experience with hyperchlorhydria has been in nervous temperaments, although not always nervous according to the popular acceptance of the term. In some cases, especially those with atony or gastrectasia, mucus has been present in considerable amount, but the burden of proof would rest heavily on one attempting to prove them other than neuroses. In particular, I recall a heavy drinker who presented the clinical picture of gastric catarrh, except that there was a history of burning pain coming on some time after meals but relieved by food. It was not very troublesome just at that time. The man had been treated for alcoholic gastritis in a hospital some months previously, but since then had been totally abstinent.

One hour after 30 grammes of bread and 300 c. c. of water had been given, free HCl was .18 per cent. and total acidity .25 per cent. The greenish contents contained much mucus. Twenty-five c. c. of filtrate required over five hours to dissolve .05 gramme of the white of hard-boiled egg at 40° C. Two days later an analysis gave the same results. Lavage sharpened the appetite, improved the catarrhal symptoms, and increased the burning. One week from the first analysis an examination under identical conditions gave 145 c. c. of contents, slightly greenish in color, with considerable mucus. Free HCl, .241 per cent.; total acidity, .31 per cent. Digestive test required three hours, the normal period. In other words, we were clearing up a gastric catarrh which obscured the usual condition, hyperchlorhydria.

The severity of subjective symptoms is not a reliable index of the degree of acidity in different cases nor in a given case at different times. It may be marked, and the acidity within normal limit. This points to hyperesthesia, which seems to be present in these cases. On the contrary, a great increase in the acidity is usually attended by a corresponding aggravation of symptoms.

In a given case, if the environment can be so controlled as to give the greatest nervous relaxation and avoid nervous tension, the prognosis is better. In short, to do the best for these sufferers, frequently one must treat them as neurasthenics. He must understand them, their history, their daily lives, so that he can assist them to live without unnecessary expenditure of nervous energy and encourage to healthy activities. How difficult this problem, where change of environment is impossible, is known to us all. On the whole, proteid diet has been most suitable, especially in bad cases. Raw eggs between meals have been very helpful in certain cases.

[1] Read before the Suffolk District Medical Society, Section for Clinical Medicine, Pathology and Hygiene, October 18, 1899.

We have found medicinal treatment discouraging as regards cure. Of local remedies, alkalies, bismuth and nitrate of silver have been tried. Of remedies intended to act through the nervous system, nux vomica and bromide. Nux vomica has seemed to decrease the percentage of acid in certain cases and improve the motility, but has increased the discomfort, except in one case, and there the result was quite brilliant. I will refer to the case briefly:

A man thirty-one years of age, with an excellent family history and past history, has been engaged in exacting mental work for several years. He occupies a very responsible position and has acquired the pernicious habit of devoting his meal times to mental work and, at the same time, satisfying completely a never-failing appetite. For three years a history of digestive disturbances. About an hour after taking food, especially at noon, he experienced a burning sensation, distention and belching, and most annoying of all, a sensation of weight, as if the stomach did not empty itself. This would last almost or quite to the next meal. Occasionally it would be present all the forenoon and recently several times late in the forenoon he has vomited his breakfast. Acid things and pastry increased the burning. Bowels irregular. Frequently a restless night. Lost much weight. Recently a trembling of the hands had annoyed him.

Physical examination. — Expression troubled and careworn. Chest, negative; abdomen prominent. Right kidney easily palpated. Stomach in normal position. Distended with CO_2 its lower border was one and one-quarter inch below umbilicus. Filled with water its lower limit was two and one-quarter inches below umbilicus. When slightly distended with gas or containing a small amount of water the stomach was considerably smaller, being markedly atonic but only moderately dilated.

Nux vomica was given and the dose gradually raised from 10 drops three times daily to 20. Habits, exercise and diet were regulated. Improvement was prompt. Treatment commenced early in May, and by August, when he started for a bicycling trip on the Continent, the gastric symptoms had nearly disappeared. At that time the stomach was empty six hours after a mixed meal given in the morning, although the salol test gave negative result at two hours and positive at thirty and a half hours. The acidity was moderately reduced under treatment, as judged from five analyses, and motor power improved. Early in September my patient wrote that there were no digestive symptoms, and to-day I received the same report.

From a practical point of view, control of subjective symptoms is the chief object of treatment. In this connection I wish to give a limited experience with nitrate of silver. I have not attempted a review of the literature on the subject. Riegel [2] recommends its trial in severe cases. It is to be given by mouth, or the stomach washed out with a solution (1–1,000), and this in turn followed by thorough washing with water. Nitrate of silver has been tried in three of my cases. In two, one-quarter grain in one-half ounce of distilled water was given twenty minutes before breakfast. One case is doing well. The other reported some improvement after two weeks, but it seemed as likely due to diet, regular exercise, and a more rational mode of living. From the fasting stomach in the morning I then obtained 10 c. c.

[2] Nothnagel's Sp. Path. und Ther., xvi.

of fluid with about .1 per cent. free HCl. The conversion of nitrate to chloride presumably caused the failure. Where there is continuous secretion of acid gastric juice thorough lavage should precede the administration of silver nitrate. This precaution is manifestly necessary, but I have not seen it mentioned. If lavage is impracticable we depend on bismuth and alkalies instead of silver nitrate. The neutralization of the acid instead of lavage will occur to everybody, but there is no means of judging the amount of alkali necessary. An excess of bicarbonate of soda, for instance, would convert the nitrate of silver into the oxide without local action, according to the equation: $AgNO_3 + Na_2CO_3 = Ag_2CO_3 + 2NaNO_3 = Ag_2O + CO_3 + 2NaNO_3$. Where the fasting stomach contains acid juice the equation, is, of course: $AgNO_3 + HCl = AgCl + HNO_3$, and in our experience the treatment fails.

Mrs. S., thirty-six years of age, consulted Dr. W. N. Bullard, December 6, 1898, and he kindly referred her to me.

F. H. Negative, except that three sisters have "weak stomachs."

P. H. In Massachusetts General Hospital nine years ago with pelvic abscess, and while there vomited blood during two days; was menstruating. Five years ago, Dr. H. O. Marcy removed the appendages for double pus tube. Recently Dr. Marcy kindly wrote me that he considered it a case of gastric ulcer. For a year after the operation she menstruated a little each month and then none for three years. In these nine years, and especially during the three when menstruation was absent, the patient vomited "coffee grounds" and bright blood frequently. The hematemesis occurred, so far as she could judge, when menstruation would naturally have occurred. Much of the past nine years has had heartburn and sour stomach. During an attack of hematemesis and the two or three preceding days, her stomach would feel as if it contained "live coals." For three or four years has drunk two cups of hot water morning and evening and vomited. It has given the greatest relief and she "couldn't get on without it." Food and tea relieve the burning pain. Very constipated. Eight weeks ago, menstruated one day, and for seven weeks the water vomited morning and evening contained "coffee grounds" and some bright blood. For a week, vomitus very acid, but not bloody. Burning continues. Not subject to epistaxis.

Physical examination. — Well developed, fairly nourished. Face, tongue and mucous membrane of mouth pale. Expression drawn. Pupillary and other reflexes normal. Repeated laryngoscopic examination failed to show any source of bleeding. Remainder of examination negative, except moderate epigastric tenderness with one very tender point in extreme left of epigastrium. This point had been tender whenever blood was raised. Lower border of stomach distended either with air or water reached a little below umbilicus. Position of stomach normal.

Analysis No. 1. — One and one-quarter hours after a test meal of bread 70 grammes, water 300 c. c., amount contents 150 c. c., containing a small amount of brown material assumed to be digested blood. No chemical test made and no blood corpuscles seen in microscopic examination. Free HCl, .15 per cent; total acidity, .27 per cent.

Patient was in bed three weeks on diet of peptonized milk and there was almost an absence of symptoms. Milk was peptonized because otherwise it seemed to cause distress, and several times was vomited in thick curds. Also, it was hoped that more acid might be combined, as Professor Chittenden has shown to be the case with peptones. During the fourth week she commenced to sit up; burning pain with frequent headache returned; and, as formerly, she found temporary relief by drinking two cups of hot water morning and night and vomiting. During this week a thorough trial was given the "gastric sedative" mentioned in the article on this subject in the "American System of Practical Medicine," consisting of two parts, by weight, of cerium oxalate, four parts of bismuth subcarbonate, and eight parts of light carbonate of magnesium. The relief was so temporary that my patient pronounced its further administration useless and asked to be excused from bothering with it. The diet had been increased only by the whites of eggs.

January 7th. Tincture nux vomica was commenced in ten-drop doses and gradually increased.

January 8th. There commenced at noon an unusually severe attack, consisting of headache, gastric distress, a strangling sensation, vomiting, and occasional darting pains referred to the stomach. In the afternoon I siphoned out the remains of one-half glass of peptonized milk drunk two hours before, and then washed out the stomach thoroughly. There was no blood. The analysis was: Free HCl, .226 per cent.; total acidity, .387 per cent.

Until March 14th the headaches were frequent. The burning sensation was severe and persistent, being relieved temporarily by the hot water and by food. Raw eggs taken between meals gave temporary relief. By successive trials, the largest dose of nux vomica to be tolerated was determined. The maximum dose was reached gradually and maintained while practicable, as judged by the nervous symptoms. Then it was reduced gradually and gradually re-established after the unpleasant symptoms had disappeared. The gastric symptoms were not relieved by the nux vomica, while the patient was much more nervous than before its administration. The outlook seemed discouraging. The history of successive attacks of hematemesis during nine years, and the sharply localized point of tenderness, which had been the same in all attacks, pointed strongly to a recurrent ulcer. Vicarious menstruation could be excluded fairly after the seven weeks' duration of the last hematemesis. In view of the almost continuous suffering from acidity for nine years, I seriously considered the advisability of an exploratory operation with a view to excision of the ulcer scar.

In one of the medical journals, I noticed nitrate of silver recommended for gastric irritability with or without ulcer; one-fourth grain was to be administered in one-half ounce of distilled water twenty minutes before breakfast, or the stomach was to be washed out with a solution (1-1,000) and that followed by a thorough washing with water. (I regret that I am unable to give the reference. It was to some digestive work.) Already lavage had been substituted for drinking and vomiting hot water. After lavage each morning, with occasional omission of two or three days, one-fourth grain of silver nitrate in one-half ounce of distilled water was poured through the tube. At this time the gastric symptoms were overshadowed by a train of symptoms commencing some days before the administration of silver nitrate, namely, frequent desire to micturate and some pain. Twenty-four hours' amount

of urine was 18 ounces, and a few days later only 11 ounces. Later, what was apparently renal colic supervened. Patient was put to bed on milk diet. As the urine remained scanty in spite of diuretics, Dr. Ogden examined and reported no evidence of renal disease, confirming the result of my own analysis.

During the three weeks' confinement to bed lavage seemed impracticable, and as bromide was indicated for the patient's nervousness, it was pushed for a possible beneficial effect on the gastric symptoms. The latter were not improved, and April 15th lavage and silver were resumed, and, with an occasional precautionary omission, have been continued to date.

May 3d. Dr. Quackenboss ordered glasses for a moderate degree of hypermetropic astigmatism.

May 5th. One hour after bread, 35 grammes, water 300 c. c., the amount of stomach contents was 45 c. c. There was previous lavage. Free HCl, .248 per cent.; total acidity, .321 per cent.; 25 c. c. filtrate dissolved, .05 gramme of white of hard-boiled egg in three and one-sixth to three and one-half hours at 40° C.

At this time the symptoms were not very marked and steadily diminished, being absent during June, July, and until August 20th. For two months before the latter date all restrictions on diet were disregarded by the patient. She fairly revelled in fresh tomatoes with pepper, vinegar and salt, stewed tomatoes seasoned with pepper, pickles, sour apples and grapes. I never saw her so happy as one day after she had eaten, without symptoms, a boiled dinner and a sour apple. She gained in weight and spirits.

August 7th. The fasting stomach contained 30 c. c. of yellowish-green fluid, acid to litmus. Free HCl, absent; total acidity, .066 per cent. Bile absent. This was the usual amount of fluid removed in the morning before breakfast. A test meal of 30 grammes of bread and 300 c. c. of water was then given and in one and one-sixth hours 110 c. c. removed, not remarkable in appearance. Free HCl, .102 per cent.; total acidity, .219 per cent.; lactic acid, a trace; filtrate, erythrodextrin; microscopic, yeast and nothing else to note; digestive test, four hours, twenty-seven minutes, at 39° to 40°. The stomach, filled with water, reached to within one and three-fourths inches of the umbilicus, being decidedly smaller than in December. Also, in order to empty the stomach completely, it was necessary to pass the tube a less distance.

August 20th. Headache, nervous, tender breasts, a sleepless night. No gastric distress.

August 21st. Ate tomato soup for supper, vomited in the night, and in the morning washed from her stomach some of the soup. June 13th, in the morning, the stomach had contained banana eaten the previous evening. These were the only times that macroscopic remains of food were present before breakfast.

August 29th. The fasting stomach this morning contained one ounce of yellowish-green fluid and some mucus. No macroscopic food remains. Free HCl, .113 per cent.; total acidity, .212 per cent.; filtrate, no reaction with IKI; digestion, three and two-thirds hours Microscopically, no blood, few starch grains, as shown by their appearance and behavior to IKI. No muscle fibres. Much pavement epithelium, one small clump of columnar epithelium, with quite frequently a polynuclear leucocyte and occasionally a salivary corpuscle.

August 29th. One hour after bread, 30 grammes, water, 300 c. c., amount contents, 72 c. c. Appearance and odor not remarkable. Free HCl, .212 per cent.; total acidity, .277 per cent.; lactic acid, absent; filtrate, erythrodextrin; digestion, four hours. Microscopically, no blood, yeast not increased and nothing of importance.

September 16th. Patient reported that the acidity had been somewhat troublesome since August 20th, three weeks. Incidentally, she remarked that she felt some burning at that moment, and I allowed her to siphon out her stomach contents. Three hours previously she had eaten, among other things, fish chowder and stewed tomatoes. The amount was 88 c. c. Free HCl, .303 per cent.; total acidity, .526 per cent.; lactic acid, absent; digestion, four hours.

September 26th. Patient reported that the acidity was very troublesome from the 16th to the 22nd of September, but since then less troublesome. The dose of silver nitrate was increased from one-fourth grain to one-half grain September 20th. Marked amelioration of symptoms was noted by the 23rd, and three days later a return to one-fourth-grain dose seems justifiable. This morning two ounces of yellowish-green fluid was siphoned from the fasting stomach. Free HCl, .146 per cent.; total acidity, .248 per cent.; digestion, three and three-fourths hours; lavage to-night.

September 27th. Same amount of fluid and of same appearance. Gastric symptoms still improving. Free HCl, .19 per cent.; total acidity, .26 per cent.; digestion, three and one-half hours; lavage to-night.

September 28th. Comfortable yesterday and perfectly comfortable this morning. Fasting stomach contained two ounces of colorless fluid. Free HCl, .314 per cent.; total acidity, .380 per cent.; digestion, three hours, fifty-two minutes. After lavage, gave test meal of bread, 30 grammes; water, 300 c.c. Amount of contents in one hour, 48 c. c. Free HCl, .27 per cent.; total acidity, .34 per. cent.; filtrate, erythrodextrin; digestion, three and one-fourth hours; lavage at night omitted.

October 4th. Since last analysis not much discomfort. Yesterday patient ate roast lamb at 4 P. M. and lamb stew at 8.30 P. M. This morning, fasting stomach contained two ounces plus of yellowish-green fluid with more sediment than usual, but no macroscopic food remained. Free HCl, .242 per cent; total acidity, .329 per cent. Microscopically, occasional striated muscle fibre and starch grain. No blood. Considerable pavement epithelium. Few yeast cells. Frequently a salivary corpuscle.

October 11th. Almost no discomfort since last analysis. Perfectly comfortable at present. Cold boiled ham and bread for supper yesterday. This morning, fasting stomach contained 10 c. c., acid to litmus, giving a faint brown with Congo-red paper; no reaction for free HCl. Total acidity, .095 per cent. Microscopically, no muscle fibre, rarely the remnant of a starch grain, as shown by IKI; frequently a polynuclear leucocyte, showing the entire cell, and a salivary corpuscle. Considerable pavement epithelium.

The case is apparently under control again, or quiescent.

The disadvantage of this form of treatment in the presence of continuous secretion is the necessity of using a stomach tube. In the case just reported lavage in the morning was done by the patient with

satisfaction. Also we must remember the possibility of argyria and omit occasionally.

Besides these three cases I have followed this treatment in a few cases in the practices of friends. So limited an experience is not convincing to me, but suggests the advisability of giving the treatment a thorough trial. Apparently it has markedly diminished the gastric sensitiveness in two of my cases, whether or no it has affected secretion of acid.

I trust that my experience may be supplemented by the favorable or unfavorable experience of others present, and may lead some to assist in determining the value of silver nitrate in hyperchlorhydria.

A SIMPLE METHOD FOR THE QUANTITATIVE ANALYSIS OF THE GASTRIC CONTENTS FOR USE IN CLINICAL WORK.

BY HENRY F. HEWES, M.D., BOSTON,

Physician to Out-Patients at the Massachusetts General Hospital and at the Carney Hospital, Boston; Assistant in Chemistry at the Harvard Medical School.

In my article upon the analysis of the gastric contents published two years ago in the JOURNAL, I suggested certain modifications of the Töpfer method of quantitative analysis of the contents, which was at that time the most practical method of analysis for use in clinical work.[1] These modifications were:

I. The addition of a second test for free hydrochloric acid which could be utilized at the same time as the dimethyl test of Töpfer and serve as a control test to ensure a more accurate record on this point.

II. The substitution of the Congo-red test for the alizarin test in the estimation of the total organic acids plus acid salts.[2] Experience had proven to me as well as to many others,[3] that accurate readings with this dimethyl test and the alizarin test uncontrolled were in gastric contents often impossible and I sought by these modifications to remedy these weaknesses in the original Töpfer method. During the last two years I have succeeded by attending to these modifications in developing and approving by extended use a quantitative method of analysis, at the same time more accurate and more simple than the original method, or the method as first modified by me. The details of this new method are as follows:

I. *Total free HCl.* — Measure off five cubic centimetres of contents after shaking. To this five cubic centimetres of the unfiltered contents in a test tube add a few drops of Töpfer's reagent (a one-half-per-cent. alcoholic solution of dimethyl-amido-azo-benzol). If free hydrochloric acid is present, the mixture will assume a carmine-red color. As a rule, where the acid is present, one drop will give the clear red color. In some cases, however, the addition of three or four drops is necessary.

To this red mixture a decinormal solution of sodic hydrate is added by titration until the red color gives place to an orange or bright yellow color. The number of cubic centimetres of the soda solution necessary to bring about this result are then read off. By multiplying this number by .00365 gramme, the amount of free hydrochloric acid in the five cubic centimetres of contents is obtained and from this record the grammes of free HCl per hundred (per cent.) or per thousand may be reckoned. As it is sometimes difficult to determine the exact point at which the red color disappears in this titration, it is well to control this test by another more delicate test for free HCl. When enough soda has been added to leave but a very faint red color in the mixture, a drop of the mixture should be mixed upon a white evaporating dish with a drop of a saturated alcoholic solution of 00 tropeolin, and the dish warmed (not heated intensely) over a flame. As long as such a mixture gives a purple color upon evaporation, the free hydrochloric acid in the contents is not yet neutralized. When the purple color fails the acid is neutralized. By thus depending upon the Töpfer test until near the end of the reaction and upon the tropeolin for the last steps, we obtain a very accurate quantitative estimation of the free hydrochloric acid.[4] For rough work, for results within .01 per cent. of the accurate result, the Töpfer test suffices.

II. *Total free acids plus acid salts.* — To the same five-cubic-centimetre mixture of gastric contents in which the free hydrochloric acid has been neutralized continue to add the decinormal soda solution until a drop of the mixture fails to color Congo-red paper (paper prepared by dipping filter paper into a five-per-cent. aqueous solution of Congo red and drying). When the mixture fails to color the Congo paper, all the free acids, organic and mineral, also the acid salts (acid phosphates), are neutralized. By taking the record of the soda used up to this point the quantitative estimate of the total free acids plus acid salts in the contents can be obtained in the same manner as in the estimation of the total free HCl. If in performing this Congo test the reaction point is passed, the paper is turned a brighter red than its original color. It is thus easy to control the accuracy of this test.

III. *Total acidity.* — To the same five-cubic-centimetre mixture of contents in which the free hydrochloric acid and the other free acids and acid salts have in turn been neutralized add two drops of a one-per-cent. alcoholic solution of phenolphthalein. Continue to add the soda solution until a deep red color of maximum intensity is obtained. The appearance of the deep red color indicates the presence of an alkaline reaction, that is, that the neutralization of all the acid elements of the contents is accomplished. From the record of the soda solution used to accomplish this result we estimate the total acidity. Care must be observed in performing this last step of the estimation to develop the deepest red color which can be obtained. As long as the top of the mixture takes a deeper color after the addition of a drop of the soda than the rest of the mixture the end reaction has not been obtained.[5]

This analysis gives us a qualitative test for free hydrochloric acid, and a quantitative estimation of the total free hydrochloric acid, the total free acids plus acid salts, and the total acidity. By subtracting the total free HCl (I) from the total free acids plus salts (II) we obtain a quantitative estimate of the total organic acids plus acid salts (IV). By subtracting

[4] The tropeolin test is used as it gives no color reaction with the Töpfer reagent; phloroglucin vanillin gives a red color with this reagent even in the absence of free HCl.

[5] Owing to mechanical obstruction some of the acid in the particles of contents is not at once neutralized by the acid, so that enough extra soda to give the deep red color – combine with all the phenolphthalein is added to allow for this acid. Upon standing well stoppered, the mixture turns a fainter red as the hidden acid is liberated.

(II) the total free acids plus acid salts from (III) the total acidity, we obtain the total combined acids (the total combined HCl in cases where free HCl is present) (V). By adding this total combined HCl (V) to the total free HCl (I) we obtain the secreted hydrochloric acid (VI).[6]

This analysis can be accomplished in five to ten minutes. It necessitates for apparatus a burette, an evaporating dish, a lamp, a test tube and a glass rod. The necessary reagents are (1) A decinormal soda solution; (2) one-half-per-cent. alcoholic solution of dimethyl-amido-azo-benzol; (3) Congo-red paper — filter paper soaked in a five-per-cent. aqueous solution of Congo red; (3) a one-per-cent. alcoholic solution of phenolphthalein; (4) a saturated alcoholic solution of 00 tropeolin. The estimations should be made twice, and the records of the tests with the second mixture of contents taken as final. For this estimation is made with an approximate idea of the results to be obtained already in mind, so that there is less waste of material in the process. The simplicity of the method admits of the employment of this quantitative analysis of the gastric contents as a routine method of diagnosis in private practice and in out-patient hospital work without undue sacrifice of time or labor.

In cases in which free hydrochloric acid is present to the Töpfer test, this analysis includes, with the exception of the qualitative test for lactic acid,[7] all the tests which are necessary in ordinary clinical work. Where the Töpfer test is absent or doubtful the qualitative test for free HCl must be tried with 00 tropeolin, Boas resorcin reagent and phloroglucin vanillin. Where a trace is discovered by one of these tests which could not be determined by the Töpfer test, the amount present is recorded as a trace, it being too small to admit of a definite quantitative determination.

Methods of analysis in cases with no free HCl; qualitative test for combined HCl. — In cases in which no free hydrochloric acid is present by any of the qualitative tests the contents are first tested with Congo-red paper. A positive test shows the presence of free acids (in this case organic acid) or of acid salts or of both. Five cubic centimetres of the contents is then estimated with the soda solution against Congo red (II) and phenolphthalein (III) in turn, and the total free acids plus acid salts and the total acidity determined.

If no free acids plus salts are present the contents are first tested with blue litmus. If the test is positive the presence of combined acid of some kind, either mineral or organic, is proven. Five cubic centimetres of the contents is then estimated against phenolphthalein to determine the total acidity (III).

In cases in which no free hydrochloride acid is present and the contents are still acid, it is of much importance to determine whether or not the combined acid present or a part of it is combined hydrochloric acid. For by this determination we ascertain whether or not any hydrochloric acid is secreted; that is, whether the acid-secreting cells of the stomach suffer from a total loss of function or a simple diminution of this function below normal. This fact may be ascertained in a simple manner by subjecting the contents to the qualitative test for chlorine. except that present in the form of inorganic chlorides, known as the Ewald-Sjoqvist test.

VII. *Test for combined hydrochloric acid in the absence of free hydrochloric acid.* — Ten cubic centimetres of the contents is mixed with a pinch (half a saltspoonful) of barium carbonate. This mixture is evaporated and the residue fused to a red heat in a platinum crucible (fused to a red heat only). The fused mixture is treated with boiling water. The mixture is filtered. The filtrate and wash-water together should amount to about 30 cubic centimetres. To this filtrate (cooled) from five to ten cubic centimetres of a saturated solution of sodium carbonate is added. If chlorine in the form of organic chlorine compounds (acid albumins, peptones) is present in the original mixture a white precipitate will form in this filtrate.

When this barium carbonate test is positive, then we know that some of our combined acid is combined hydrochloric acid and that the disturbance of the secretion of acid present is due to a diminution rather than a total loss of function of the secreting cells. This is a fact of considerable importance in our knowledge of the case. This Ewald-Sjoqvist test is very simple. It occupies about half an hour. It necessitates for apparatus a platinum crucible and a Bunsen lamp. The necessary reagents are, (1) barium carbonate CP; (2) saturated aqueous solution of sodium carbonate. All methods of quantitative estimation of the total combined hydrochloric acid in the absence of free hydrochloric acid, which are of sufficient accuracy to be of use, are too difficult of application for use in ordinary clinical work.

I have employed the above plan of analysis as a routine method in all cases of gastric affections in my out-patient clinics for two years. The results from the point of view of diagnosis and of therapeutics and of acquiring a more thorough understanding of the disorders of the stomach have amply repaid the labor.

[6] This total hydrochloric-acid record is the index of the secretory force of the stomach, much more accurate than the record of total acidity or total free HCl.

[7] To test for lactic acid two cubic centimetres of the filtered contents is added to five of a colorless solution of ferric chloride. If this test is negative lactic acid is absent. If the test is positive (if a lemon-yellow color appears in the ferric-chloride solution) the test must be confirmed by performing this ferric-chloride test with an ethereal extract of the contents. If this test is positive, lactic acid is present. If it is negative, the color in the preliminary test was due to some substance other than lactic acid.

Clinical Department.

THREE UNUSUAL CASES OF ANGIONEUROTIC EDEMA IN INFANCY.[1]

BY JOHN LOVETT MORSE, A.M., M.D., BOSTON,
Assistant Visiting Physician at the City Hospital and Assistant Physician at the Infants' Hospital, Boston; Assistant in Clinical Medicine, Harvard Medical School.

ALTHOUGH angioneurotic edema is occasionally met with in infancy it certainly cannot be regarded as of common occurrence. The usual seats are the lips and cheeks or the external genitals. The extremities are seldom involved. The location of the swelling and the apparent cause in two make the following cases of unusual interest:

CASE I. Constance M., twenty-three months, woke up on the morning of March 9, 1898, with her left arm moderately swollen. It was not painful and she

[1] Read before the Suffolk District Medical Society, Section for Clinical Medicine, Pathology and Hygiene, October 18, 1899.

used the arm freely. There had been no known injury or exposure. The swelling of the forearm increased during the day and the next morning the hand was also much swollen. She was otherwise perfectly well.

I first saw her at this time. The left forearm and hand were much swollen from the elbow to the second phalanges. The surface was somewhat reddish and a trifle hot. There was moderate pitting on pressure. There was no tenderness and she used the hand and arm freely. There was no lesion of the surface and no enlargement of the axillary glands. The pulse was normal. The arm was bandaged loosely, and on March 12th, four days from the onset, the swelling had entirely disappeared. There has been no recurrence.

Case II. Ruth B. was seven months old November 5, 1897. One morning, about this time, her mother came in from a walk and gave her her morning bath. Being in a hurry she tested the temperature of the water with her hand. It was later found to have been much colder than usual. The child cried vigorously and when taken out was shivering and blue. She soon warmed up again, but about an hour later it was noted that both her forearms and hands were swollen, bluish and cold.

I saw her soon after. As stated above, both forearms and hands were much swollen and slightly cyanotic. The skin was shiny and there was no pitting. The surface was rather cool. There was no tenderness or pain and the arms were moved freely. There was no enlargement of the axillary glands and the radial pulse was normal. The heart and urine were both normal.

The swelling disappeared, without treatment, in two days. A few weeks later, however, it recurred, evidently as the result of sleeping in a cold room with the arms exposed. At this time it lasted about two weeks, disappearing gradually. All the rest of the winter and spring, until the return of warm weather, the swelling recurred on any exposure to cold. It rarely lasted more than a few hours or a day or two at a time, however. Thick mittens, worn out of doors and at night, decidedly diminished the frequency and severity of the attacks. There was no return of the swelling during the winter of 1898–99. In October, 1899, however, she came in rather late on a cool afternoon, not having worn mittens as the weather was warm when she went out, with her right hand and arm swollen as before. It went away in a few hours and has not returned since.

Case III. Laura M. was brought to the Medical Out-patient Department of the Infants' Hospital, March 15, 1899. She was then four months old. She was born at full term, head presentation, about three-quarters of an hour before the arrival of the doctor. Any injury to the arms at birth would thus seem improbable. Since birth the right upper extremity has frequently become swollen and purplish. During these attacks the child has seemed unable to use the arm. After from two to six hours the natural appearance and function have returned. The attacks have recurred at any time of day or night and have apparently not been accompanied by pain. The mother was inclined to attribute them to a slight injury to her right arm which she received when she was about three months pregnant! ! !

She was a large, fat baby in very good condition. The right arm was then of normal color but the student who took the history stated that while he was taking it the arm was markedly purple. It was warm and did not pit on pressure. The circumference of the right forearm was one and one-half centimetres and that of the right arm one-half centimetre greater than that of the corresponding part on the left. There were no enlarged glands in the axilla and the pulse at the wrist was normal. The heart was normal. There was no tenderness and the child moved the arm freely.

She was seen again October 4, 1899. Her aunt stated that the attacks had continued, but had been much less marked during the warm weather. She thought that there was some connection between their occurrence and the external temperature. The swelling had been much more pronounced during the last few days of cool weather. She thought that the right arm was now always a little larger than the left.

The color of the arm was then normal but it seemed somewhat larger than the left and the forearm and hand looked edematous. There was no pitting on pressure, however. The circumference of the forearm was one and a half centimetres and that of the arm one centimetre larger than on the other side. The surface temperature was normal, there was no tenderness and the arm was moved freely. There was no enlargement of the axillary glands, the pulse was normal at the wrist and the heart was normal.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

A. K. STONE, M.D., SECRETARY.

Regular meeting, Monday, November 6, 1899, Dr. R. H. Fitz in the chair.

ANATOMICAL SPECIMENS.

Dr. Beach: This photograph is from a child seven years old who was the subject of imperforate anus. The rectum ends within the vulva. The vagina is immediately above it and the meatus of the bladder immediately above that. This photograph has been taken to show the three passages, making a cloacal aperture of the vulva. She was referred to me with the idea that some surgical measure might be advisable, but the control of fecal movements was so good and there being no certainty of a sphincter to guard a new anus, I advised against interference. The child had no inconvenience from the unusual condition, which was discovered by the nurse at birth.

Dr. Beach stated in answer to a question by Dr. Vickery that the conformation of the parts was similar to what exists in the hen.

Dr. Withington: Would Dr. Beach take that position as a rule with regard to all such cases, or was there in this particular case some reason why operative interference was not called for?

Dr. Beach: It was the first time I ever saw this arrangement of the parts. As the child had lived to be seven years old, had not suffered, and there was control of the movements, I felt that in this case we had better make no interference. I have operated a number of times in cases of imperforate anus and once advised a laparotomy soon after birth, where there

was no outlet for the fecal movements and no guide for a dissection.

DR. WITHINGTON: You would not take the general position of refusing an operation in all cases where there was perfect passage for the fecal matter?

DR. BEACH: No; I should be guided by the exigencies of the case.

DR. WITHINGTON: I ask the question because I have now a child, born about six months ago, in whom there is precisely the same deformity, the rectum ending inside the vagina and there being no anus at the proper place. I had assumed that it would be necessary by and by for the child to have something done in an operative way, at any rate before reaching a marriageable age. There is absolutely no obstruction to the passage of fecal matter and the child has no inconvenience in any way. The defect was discovered a day or two after birth, and I said nothing to the mother until she got through the puerperium, and then I told her that when the child got older I presumed surgical interference would be necessary. I am interested to know it is not considered necessarily indicated in case the passage is perfectly patent and well controlled, as it is in Dr. Beach's case and in the case I have in mind. The child certainly has no inconvenience and apparently is going to have perfect sphincteric control of the rectum.

DR. BEACH: If the end of the rectum is guarded by a sphincter at the vulva, and it is dissected away from that sphincter, displacing the rectum to the middle of the ischio-rectal space, where no sphincter is found to guard it, incontinence of feces may be expected, and, it seems to me, in that case it is better to bear the ills we have than to invite others.

DR. B. TENNEY read a paper on

APPENDICITIS IN A HERNIAL SAC.[1]

DR. BEACH: I never have happened to see this complication in any case of hernia or appendix upon which I have operated, though I know it has occurred at the Massachusetts Hospital. The lesson to be drawn from the reader's paper is that all cases of hernia, or where hernia is supposed to exist, with the slightest obstructive symptoms should be very carefully investigated. My rule is contrary to past teaching, which directs, first, taxis, and, if unsuccessful, operation. Personal experiences justify me in urging exploration of the hernial sac whenever obstruction symptoms exist and being guided by the condition found. This course would surely disclose the complication described by Dr. Tenney and prevent the return of a gangrenous appendix or a gangrenous loop of the intestine to the peritoneal cavity. I am sure that this course would have saved cases that I lost in my early operations from not realizing how rapidly gangrene could occur after obstruction, and that intestine irremediably injured by a short period of constriction could easily be returned by taxis.

DR. F. C. COBB read a paper on

EPISTAXIS.[2]

DR. FARLOW: There are many mild cases of nose-bleed, which are usually considered of no consequence by the patient, but which are deserving of careful attention; the slight but recurring hemorrhages caused by blowing or picking the nose. This is usually a sign of an erosion of the septum which may lead to an ulceration or perforation, and may be the starting point for an attack of facial erysipelas. I have in mind several such cases, where the question of cause and effect seemed very clear. It is always well to examine the nasal septum of sufferers from facial erysipelas and also inquire as to the existence of nose-bleed in the past. According to my experience, nose-bleed is less common when there is deformity of the septum than in the catarrhal, especially atrophic, forms of disease of the mucous membrane where the septum is usually but little irregular.

Nose-bleed in elderly people is usually considered to be difficult to check and to be of unfavorable significance. I have a French thesis written by Tautel, who had access to the Saltpêtrière Hospital in Paris and tabulated a great many cases of nose-bleed in elderly people. He came to the conclusion that the gravity of the prognosis was much exaggerated and that the bleeding was nearly as easily stopped as in younger people. This tallies with my own experience.

With regard to how long a posterior plug can remain in place, I recall the case of an elderly lady who had suffered from a number of severe attacks of nose-bleed. One occurred the day before she was to sail for Europe, and her physician put in an anterior and a posterior plug. He went to the steamer with his patient and asked the ship's surgeon to remove the plugs on the following day. But the history of the past hemorrhages apparently made a deep impression on the surgeon's mind, for he decided not to remove the plugs until he got within sight of land, where he could have assistance if needed, and the unfortunate passenger carried her plugs from Boston to Queenstown, no evil consequences resulting, strangely enough.

It is a good plan to put vaseline on the nasal plug, or some oily substance, so that it shall not adhere to the bleeding point. Moist gauze answers the same purpose. I have found peroxide of hydrogen excellent for stopping epistaxis. In looking for the bleeding point, which is almost always on the anterior inferior cartilaginous septum, I have noticed that students are very likely to pass the speculum in such a way as to cover the bleeding point and it is thus easily overlooked. If the end of the nose is tilted up by the finger the front part of the septum can often be well seen without a speculum; and if the speculum is used it should be held in such a way as to point toward the septum, but its end should not touch the mucous membrane, otherwise it may provoke a bleeding.

I have been extremely pleased with the action of the suprarenal extract, and it seems as if I used it more than cocaine in everyday work. It is most excellent for constricting the blood-vessels and opening up the nose. Under its use I have done a great many bloodless operations in the nose, and I have not seen any unpleasant effects from it. Patients are very likely to wonder whether their nose-bleeds may not be due to polypi and mistake the inferior turbinate (which they can see in a mirror or feel with the finger) for a polypus. But hemorrhage from nasal polypi is not at all common.

The "grip" can be the cause of severe nose-bleeds, as in a series of cases reported by Dr. DeRoaldes, of New Orleans.

Nose-bleed in children may be a sign of adenoid disease, and it is always well when no erosion or bleeding point is found on the septum of a child after a

[1] See page 4 of the Journal.
[2] See page 2 of the Journal.

recent nose-bleed to see whether the blood may not have come through the nostrils from the post-nasal space.

DR. DEBLOIS: As to some points in the causation of epistaxis, I would say that whereas Dr. Cobb speaks of the rarity with which the *presence* of foreign bodies in the nose was a cause of epistaxis, it has been my experience to find that almost invariably their *removal* is followed by epistaxis, particularly if the foreign body has remained in the cavities for some time. In almost all these cases the body remains in apposition to the septum and a certain amount of mucous membrane is, to say the least, thinned, perhaps removed. When that body is removed with forceps or hook, this bleeding point remains, or rather bleeding surface, because it is usually more than a point. I had a case at the hospital in which a shell had been retained in the nose fourteen years. The whole shell appeared to be filled with granulations. The hemorrhage was very profuse.

With regard to traumatic epistaxis, the epistaxis of the prize-fighter, it makes a great deal of difference where the nose is struck — a blow from below producing hemorrhage quicker than a straight blow on the bridge of the nose.

With regard to plugging the nose, I was rather nonplussed the other day while endeavoring to demonstrate the use of Bellocq's canula, to find I tried four different noses before I found one it would go through. It appears to be a very large instrument, and of course with a large instrument, if there is a slight deflection of the septum, the introduction of the canula is very difficult. Now of course the ordinary catheter is a pretty good thing, but the Eustachian catheter is better, and in using the Eustachian catheter the twine that is used should always be waxed, because otherwise, as soon as it touches the mucous surface, enough mucus exudes to be quickly taken up with the string and further introduction becomes impossible. Now, if just an ordinary Eustachian catheter is used, the string can be poked through and seized from the other side with a pair of forceps as soon as it appears below the velum. I have once or twice been called to remove a plug from the posterior nares where there appeared to be no way of getting at it; in other words, after tying the sponge cotton on to the cord they cut it off close and had drawn it up behind the velum assisted by the finger. The end of the twine should always be left out, and instead of making a knot around the twine, if you make a loop and draw it tight and push the cotton up in that way and knot the twine in front of the mouth, of course there will be a slight discomfort from having the twine in, but you can always pull it down again by the part which comes through the mouth.

Dr. Cobb spoke of the constriction to be brought on the superior coronary artery. There is a very simple old-fashioned remedy for nose-bleed which is exactly the same thing, and that is to take a piece of cotton or paper and put it under the lip, pushing it up against the nose and then drawing the muscles of the mouth tight, which produces this constriction in the same way.

Bleeding points are concealed in some cases. There are frequently folds, not on the septum, but just below it in the vault, where the mucous membrane and the skin may very frequently form a kind of fourchette which will conceal these bleeding points, and I have frequently had to open them in order to get the cautery down into them.

In speaking of caustics, I never have found any advantage in using chromic acid. I think the galvanocautery heated to red heat is invariably the best. I have seen cases in which it was not necessary at all for the patient to blow his nose in order to cause epistaxis; people with full habit and determination of blood to the head bowing the head down will be sufficient. I remember the case of an engraver in whom as soon as he commenced work and bowed his head down the blood rushed to the head and this epistaxis would commence. It was supposed he was being saved from apoplexy. He was sent to me with supposed bleeding in the back of the nose. I thought it was there myself, but I was so fortunate as to start one of these little scales in the front of the nose, and two cauterizations completely cured the case. Injections of astringents are very valuable. I saw a case at the dispensary in which the bleeding had continued twenty-four hours. The man was struck on the nose with a billet of wood in a fight on a schooner. The nose was plugged. I could not find any bleeding points. A few injections of tannin checked the hemorrhage and he was kept under surveillance twenty-four hours, but it never returned. I think injections of tannin, particularly iced tannin, are invaluable after operation also.

As regards the polypi I can only concur in what Dr. Farlow and Dr. Cobb have said, that except in advanced malignant disease you do not find hemorrhage accompanying polypoid growth.

DR. COOLIDGE: Excepting such cases of epistaxis as are obviously caused by a neoplasm or some evident constitutional disease, the bleeding almost always comes from the cartilaginous septum. If this were universally understood a great many patients would be saved the discomfort of having their posterior nares plugged when it is unnecessary. This bleeding from the septum may be divided into two classes: (1) that which comes from some erosion due generally to picking the nose with the finger or handkerchief, leading to the formation and the tearing off of a crust; (2) perhaps the more important, that due to the breaking of an artery on the surface of the mucous membrane. On account of its anatomical position this artery cannot retract, and is not obliterated after its rupture, but may at any time bleed again, causing periodic epistaxis, which may recur for weeks or months. It seems to me to be of great importance to find the point from which the bleeding comes if possible; therefore, unless the blood is coming too fast, it is better to sponge and look with a good light to see where the blood comes from before packing. When the vessel which is the cause of the epistaxis is found, the proper treatment is to get rid of that vessel entirely, and the way to do it is to make an eschar including the vessel in it. That can be done with chromic acid, provided the nose is not bleeding at the time. A little chromic acid on a dry surface will make an eschar which will probably stop that vessel effectually. The differential diagnosis between this bleeding from one vessel and bleeding from an eroded surface ought very easily to be made simply from the presence of the eroded surface. An eroded surface should not be cauterized but covered with an ointment. If one vessel only is at fault the bleeding always comes from the same side and comes out in front if it can, unless the patient's head is thrown back. Occasionally a septum looks pretty smooth, and yet there is a weak point which is hard to see unless it is actually bleeding. This form of bleeding occurs frequently in children. A boy will often have two or three large vessels on the

septum and perhaps have nose-bleed every little while for years.

I should say, in my experience, that alcohol had a strong predisposing influence in advanced life, that the man who drinks every day is more likely to have bleeding from the septum than one who does not.

DR. CLARK: There are one or two points I want to speak of which I think have not been brought out by the other speakers, although Dr. Coolidge may have had this condition in mind when speaking of large vessels in the septum. I have seen a number of cases where the septum has presented the appearance such as one sees in acne rosacea, a congeries of large vessels on the septum, not necessarily in old people. I have seen several cases in young people. As Dr. Coolidge said, hemorrhage from these can be prevented by destroying the lumen of the vessels by application of the cautery. In regard to treatment, none of the speakers have mentioned nitrate of silver. Given a case of hemorrhage from the cartilaginous septum it is usually my custom to apply cocaine first and then a four-per-cent. solution of antipyrin, which I think is very useful in continuing the contraction caused by the cocaine. Now that we have suprarenal capsule, the value of the antipyrin solution is not so great. Then I apply nitrate of silver to the bleeding point, either fused on the end of a probe or the solid stick. I think the inflammatory reaction is less than from the galvanocautery and that the end result is fully as satisfactory.

I should like to emphasize what Dr. Cobb said about plugging the posterior nares. In my experience it is never necessary. I have never seen a case of hemorrhage from the nose where plugging of the posterior nares by means of the Bellocq sound or some similar instrument was indicated. I can imagine a case of hemorrhage from the nasopharynx where this might become necessary, but I have never seen one. Bleeding from the septum can always be controlled by packing the nose properly through the anterior nares.

DR. BEACH: There is one practical point I would like to speak of relative to the discomforts of packing a nostril, putting in the plug and taking it out afterwards, from which I have had more or less trouble. A number of years ago I looked about for something to take the place of plugging. What suggested ferric alum injections I cannot say, but they proved to be invaluable. We occasionally had cases of severe epistaxis apply for relief to the Massachusetts Hospital before the days of the throat department, and without a very careful diagnosis of the source of the hemorrhage they entered the surgical department and were classified as epistaxis, idiopathic or traumatic. I found that a saturated solution of ferric alum injected into the nostril from which the hemorrhage proceeded invariably stopped it. From that time I never had to plug the nose either in front or by the posterior nares. That was some fifteen or sixteen years ago or longer. I do not recall a case where I had to use it twice.

DR. GOODALE: In regard to the histological condition in many of these cases of nose-bleed, it has been shown that there is often a plexus of veins at the anterior part of the septum. Just why the plexus should occur at that point has not been explained. Its existence is brought into view very plainly, clinically, by the application of suprarenal extract, when with simple cocaine applications it may pass unobserved. The existence of this plexus is also shown in some cases by cauterizing one or two of the bleeding places and then examining the case later, when it will be seen that other veins or vessels of this plexus have undergone enlargement. These later may become very prominent, and if the same injury is offered by the patient of picking with the finger nail, rupture of the vessel walls and epistaxis will result. I think in a good many cases it would be advisable to watch afterwards as to the condition of affairs, and in that way be ready to head off an epistaxis by cauterizing some of the newly enlarged vessels, which can be perfectly well done.

DR. COOLIDGE: It has been suggested that it is veins that bleed, but the common bleeding in these recurrent cases is obviously arterial. It is not uncommon to see a vessel spurting, sometimes a good-sized one. I should like to emphasize what has already been said, that the more skilful the man the less often will he have to plug the posterior nares. If the bleeding comes from the nasal cavity it generally can be reached from the front, and this is much more comfortable for the patient and better in every way.

DR. FARLOW: A number of microscopical examinations have been made with reference to the connection between erosion and hemorrhage of the septum and Jacobson's organ, which, though present in some animals, is entirely rudimentary in man.

With reference to the injection of ferric alum into the nose, if a solution of it on a pledget of cotton is pressed into the nose and held against the anterior part of the septum, which is the seat of hemorrhage in nearly ninety-nine out of one hundred non-traumatic cases, we shall get all the advantage of the astringent action of the alum without its irritating effect in the back of the nose or throat, where it is not needed.

DR. BEACH: I have never observed any disadvantage except a slight irritation at the time. An interesting case of epistaxis entered the hospital to-day from a wound by a pistol ball, 32 calibre, that entered the auricle on the anterior surface, glanced by the mastoid process of the temporal bone, passed directly downward and forward into the pharynx behind the soft palate, so that I could pass a probe directly through the outside wound forward and downward back of the soft palate, where it could be felt. How the jugular vein and carotid artery escaped injury it is difficult to understand.

DR. COBB: I am sorry that in the discussion one thing which I wished to emphasize particularly, the occurrence of nose-bleed as an early symptom of Bright's disease or some form of nephritis or arteriosclerosis, has not been alluded to. I should have been glad to hear whether any of the gentlemen had had any experience of that sort, that is, where epistaxis has been the first symptom and followed by death from nephritis of any sort. I hoped Dr. Vickery might have said something about this part of the subject.

DR. F. L. JACK: I should like to emphasize one point which Dr. Cobb, I think, mentioned in his paper — the danger to the ears from plugging. As we all know, plugs removed from the nose after twenty-four or forty-eight hours are very foul. This condition would be very apt to cause an irritation in the neighborhood of the Eustachian prominence, producing a middle-ear inflammation, with all the chances of serious trouble following. However, it has been my experience that plugging the posterior nares is seldom necessary. The ears are in danger from a similar cause by plugging through the nose, although the chances are very much less.

DR. VICKERY: I have been trying to recall a case in which that led to the diagnosis. I hardly remember such a case. I have seen nose-bleed prominent in connection with somewhat advanced cardiorenal disease. I have seen a case of epistaxis from the excessive use of alcohol. I have seen it in the form of vicarious menstruation; I have seen it with profound anemia, I think pernicious anemia, and I am sure leukemia. I think a case of leukemia in the wards of the Massachusetts General Hospital finally died with nose-bleed, that is, not that any particular nose-bleed could not be stopped, but that it kept recurring and the patient grew weaker all the time. My impression is that nose-bleed also occurs with heart trouble apart from renal disease. I cannot think of a case I have seen. It seems to me a very valuable suggestion that we ought to search farther than this little ulcerated spot on the septum when a case applies to us for nose-bleed.

DR. FITZ: The question Dr. Cobb raised in reference to the relation between nose-bleed and nephritis I think was alluded to by some of the gentlemen taking part in the discussion. It has repeatedly come to my knowledge that persons with a nephritis have suffered from nose-bleed in the earlier days of the disease, and it is my impression that this symptom is generally mentioned in the text-books in connection with the description of forms of nephritis, especially of the chronic interstitial variety.

There is one other point which none of the gentlemen have alluded to, and that is with reference to the etiology of these dilated vessels in the nasal mucous membrane. The thought which has always been in my mind is that they perhaps were more likely to occur in persons who suffered from chronic nasal catarrh. I should like to know whether Dr. Cobb has made any observations with reference to this point.

DR. COBB: I have not found any reference to nasal catarrh in the etiology of such dilated vessels. I suppose irritating mucous discharge passing over the nose might cause hyperemia.

DR. FITZ: There seems to be a very plausible explanation of the occurrence of nose-bleed in cardiac cases as mentioned by Dr. Vickery, namely, passive congestion of the mucous membrane and dilatation of the vessels, associated with increased secretion from the nasal fossæ.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR CLINICAL MEDICINE, PATHOLOGY AND HYGIENE.

J. BERGEN OGDEN, M.D., SECRETARY.

REGULAR meeting, Wednesday, October 18, 1899, DR. H. F. VICKERY in the chair.

DR. J. L. MORSE reported

SOME UNUSUAL CASES OF ANGIONEUROTIC EDEMA IN INFANCY.[1]

DR. HEWES: I should like to ask Dr. Morse whether there was any coldness of the part, as you often get in the parts in Raynaud's disease?

DR. MORSE: I should say that in the first case the surface temperature was somewhat increased, and in the other two, if anything, somewhat diminished. The changes were, however, very slight.

DR. VICKERY: I myself have never seen a case of angioneurotic edema in infancy, but several cases in adults. There is now under my care a young unmarried woman who is neurotic. At present she has some febrile disturbance associated with rheumatism in the right hip-joint. Some year or two ago she had a general edema without any renal or cardiac trouble, and she was in a debilitated state. I think that she had amenorrhea at the time and she left the hospital not much relieved. She then came under the care of a doctor who was much interested in her case and, after trying one means and another of improving her condition, he found that decided improvement, with return of the menses, followed the ingestion of ovarian extract. She now has no edema. I remember another woman about thirty, also neurotic, who had edema which might well have been thought to be renal in its origin, but there was nothing wrong with the kidneys so far as we could make out on careful observation of the case, and it seemed impossible to call the edema anything but a neurotic affair. Both these cases were not so localized; they were more general. Of course there are a great many cases of localized edema of this kind. The possibility of myxedma in both of these cases was considered, but it was possible to exclude it.

DR. M. P. SMITHWICK read a paper entitled

NITRATE OF SILVER IN HYPERCHLORHYDRIA.[2]

DR. HEWES: I have had some experience in the treatment of hyperchlorhydria with nitrate of silver and I have convinced myself that it has considerable use in the treatment of that condition. My method of treating the hyperchlorhydria has been a systematic one. I have always endeavored, after determining the existence of hyperchlorhydria by chemical analysis, to treat the case as much as possible by diet, that is, I start them on a proteid diet and try to offset the symptoms purely by the use of the diet. If the patient comes back after a week or ten days with the symptoms unmitigated I use alkalies in addition to the proteid diet. When that fails I use nitrate of silver—reserving it for the severe cases. Out of perhaps 100 cases of hyperchlorhydria that I have seen I should say, without having the figures here, that perhaps 20 have failed to show marked amelioration with the diet, or the diet plus the alkalies. In some of these cases which have failed to improve or to improve markedly under the proteid diet or under the proteid diet plus the alkalies, the nitrate of silver has had marked beneficial effects, in fact, practically curative effects. I can remember four cases in which the nitrate of silver treatment was begun in the third or fourth week and in all four cases the effect of a continuous treatment with nitrate of silver for one or two months has been, as far as I know, curative as regards the symptoms of the patient. Of course, as Dr. Smithwick's paper shows, he did not, and I imagine in my cases I did not, cure the hyperchlorhydria. The last analyses Dr. Smithwick gave were higher as a matter of fact than the first. In reality the hyperchlorhydria is quite as rampant as ever, but the treatment has diminished the patient's sensibility to it, which as a matter of fact, as far as I understand it, is in our clinical terminology all that hyperchlorhydria means. You frequently see patients with free hydrochloric acid of 2.4 grammes per thousand and even more without symptoms, and you frequently see patients with typical symptoms of hyper-

[1] See page 10 of the Journal.

[2] See page 6 of the Journal.

chlorhydria with free hydrochloric acid of .5 of a gramme per thousand.

In regard to what the specific action of nitrate of silver is in these cases I have no very clear idea. Of course it has an astringent action, but it is hard to see how one-fourth grain given every morning can have any permanent action upon the stomach. All we have is our clinical evidence that some cases that have resisted other treatment have improved with nitrate of silver. I have used one-third of a grain once and sometimes twice a day and kept it up a month and if necessary two months. The chief symptoms which the cases have ordinarily suffered from have been pain or distress and frequently a stasis of contents, with vomiting, and the two apparently disappear together. Many cases have no vomiting but heartburn and pyrosis. It is thought by writers on the subject of hyperacidity or hyperchlorhydria that the stasis which occurs is due to spasm of the pylorus induced by the acidity; and in relieving the one you relieve the other. I have had very good evidence in a number of cases that this was so. I remember one case, in which a girl had suffered attacks of pain in the stomach one-half hour after food for two or three months and for the last month vomited large amounts every two or three days. It was quite evident there was an accumulation which relieved itself by vomiting. The attacks of pain would become more frequent up to the third day, when there would be pain almost all the time and finally vomiting. That case was entirely cured by the use of proteid diet, and large amounts of alkalies given whenever she had the pain. I practically kept the acidity neutralized as much as possible and from the time she began to take the alkalies p. r. n. she ceased to have the pain. There, apparently, the careful administration of alkalies controlled the hyperacidity in the sense that it controlled its effects.

DR. COOLIDGE: There are only three cases of hyperchlorhydria I can report, which have been treated by nitrate of silver. Two were not improved, while the third was very much improved. All had resisted other forms of treatment. Nux vomica and also alkalies and bismuth were given but without effect. The one which was benefited the most was the worst of all, the one that had the most pain. When this man came to the hospital he had a box of morphine pills which had been given by a physician, the pain at times being so great. He had been under treatment a long time, and when he came in, said he came in because his stomach was "too acid." There was no examination of his stomach contents made after fasting, but there was an increased amount of hydrochloric acid after the test meal. Within three days of the time he commenced taking one-fourth grain of nitrate of silver, he commenced to improve and the improvement continued. He took nitrate of silver regularly a few weeks and then only once in a while. The two cases that failed both had large amounts of hydrochloric acid in the fasting stomach. This gives rise to the question as to whether nitrate of silver put into a stomach when there is hydrochloric acid present is going to have any local effect or going to do any good. The same thing was quite true in these cases, as Dr. Hewes found, that there was no diminution in the amount of hydrochloric acid, but simply in the sensitiveness, so to speak, of the stomach.

DR. VICKERY: I should like to ask if Dr. Hewes administered the nitrate of silver in the same way Dr. Smithwick did.

DR. HEWES: In some; and in others I let the patient take it in one-half glass of water on getting up in the morning. When I gave it twice a day I gave it early in the morning and then at a period in the afternoon when the patient had fasted at least four hours after a simple meal. The patient took it out of a glass of water in that case.

DR. SMITHWICK: I would like to ask Dr. Hewes if he happens to recall how much acidity was found in the fasting stomach in the cases in which nitrate of silver failed.

DR. HEWES: I can recall one perfectly well. There was none. I remember another, in which the acid was about 1.5 grammes per thousand of free hydrochloric acid. That was a case with hypersecretion. Here I used lavage before administration. Of course, there are cases in which nitrate of silver fails, cases in which everything seems to fail.

DR. SMITHWICK: I should like to ask Dr. Ogden if, where it seems advisable to push nitrate of silver, there is a practical way of estimating whether elimination is sufficiently rapid before you begin to get evidences of argyria. Would the urine be a practical test?

DR. OGDEN: I am not aware that any definite information can be obtained from the urine under such circumstances.

DR. VICKERY: The neurologists have that question to consider and I think in some text-books it is stated how many grains it is safe for an individual to take. Up to a certain limit there is safety from argyria.

DR. HEWES: Einhorn gives this nitrate of silver as a spray with special apparatus and claims he gets better results in that way. He sprays a 1–1,000 solution in the stomach, using a movable end to the tube. In that way the action is more direct than the way we give it.

DR. VICKERY: I should think that some of these cases would react to any rather novel and striking means of treatment, even if it were perhaps not physiologically effective. I should like to ask Dr. Smithwick or Dr. Hewes if they have ever seen relief upon exclusive milk diet.

DR. SMITHWICK: Oh, very much. In the case I reported at greatest length on milk diet, the symptoms practically disappeared.

DR. VICKERY: I had a case that was refractory until that was done.

DR. SMITHWICK: It seems to me peptonized milk has worked better than ordinary milk. Some of these cases claim they cannot take milk; that they vomit it in thick curds.

DR. HEWES: I think as a rule you will not get as good results with a milk diet as with stronger proteids, except in cases where the hyperchlorhydria is due to the irritation of an ulcer. Meat or eggs are preferable from the point of view of utilizing the superfluous acid or even things like somatose and peptones, if the patient can bear them. Milk has a low hydrochloric-acid-combining power, practically speaking, in proportion to its bulk.

DR. VICKERY: I myself would like to speak of a case, if the gentlemen have the patience to hear about it, that has interested me. It is a striking case. It was a man seventy years old who suffered very much from pain in the epigastrium, had lost forty pounds' weight and had a distinct cachectic appearance, not mere pallor, but a yellowish pallor. His tongue, however, did not look as the tongue in a great many cases

of abdominal cancer does. It had the normal amount of epithelium upon it and was not very bright red and I noticed that fact and record was made of it. No lump could be felt by me. This man vomited coffee-ground material. He had a mere trace of hydrochloric acid in his stomach one hour after a test breakfast and a good deal of lactic and butyric and acetic acid. He also had a leucocytosis, and no increase of the white cells after digestion. He suddenly had a very severe pain, his pulse changed from 80 to 150, his abdomen became distended, rigid, and tender, and the diagnosis of a perforation was made; but in consultation Dr. J. C. Warren, Dr. Maurice H. Richardson and myself all agreed that he was not a fit subject for operation; his strength was not sufficient for it. His sufferings were mitigated with morphine and the autopsy showed a perforated ulcer of the duodenum without any sign of cancer whatever. It was on the posterior side, deep in, and could not have been got at by operation, the pathologist, Dr. Wright, thought. If there had been no autopsy I should have felt sure it was a case of carcinoma, and in going over the ground I cannot exactly see why he is excusable for not having a carcinoma instead of an ulcer. Perhaps you gentlemen who devote so much time to digestive disturbances may be able to make some instructive remarks upon my report of this case.

Recent Literature.

The Nervous System and its Diseases. By CHARLES K. MILLS, M.D. Pp. xxx, 1,056, with 459 illustrations. Philadelphia: J. B. Lippincott Co. 1898.

Although not definitely indicated on the title page, this is really the first volume of an exhaustive treatise on the diseases of the nervous system which is destined on its completion to take high rank among the larger works upon the subject. The present volume deals with the anatomy of the nervous system, the general pathology, etiology, methods of investigation and therapeutics, and the diseases of the brain and cranial nerves, with the exception of mental diseases. As all familiar with American neurology for the last twenty years might safely have predicted, the work is exhaustive and the fruit not only of wide study but of prolonged original investigation in clinical neurology. The section on Anatomy is well written and reasonably full, but we believe it would be more helpful to the student if the embryological development were made more prominent and the neurone theory brought more into the foreground, so that he might more readily obtain a few simple, fundamental conceptions upon which to group the mass of facts presented. Curiously enough no mention is made of the internal anatomy of the cell body of the neurone as made evident by Nissl's method. It was to be expected, but none the less to be regretted, that the writer should adopt the cacophonous jargon of Wilder, which is so well calculated to make cerebral anatomy unintelligible except to the adept, but he has furnished the reader with a key to these weird terms, so that the student's task is simply made a trifle more difficult yet not impossible. The chapter on General Therapeutics is full of helpful suggestions for the practitioner, the results of the wide experience of many years. The section on Methods of Examination is unfortunately too condensed. The importance of careful training in clinical examination is so vital that we regret that the author has not given the student fuller details. Above all, the study of the mental symptoms, so often neglected and for which so little help is usually to be obtained from text-books, receives too little consideration, unless the author intends to dwell upon it more elaborately in the second volume — a task which we trust he will undertake.

The remaining chapters, upon the Diseases of the Brain and Cranial Nerves, are elaborate and complete. Upon certain points of controversy we might be disposed to differ with the author, but although his own views are positive he deals fully and fairly with the opposing views and presents the arguments on his own side without exaggeration. In the enormous wealth of material contained in these chapters it sometimes seems as if the fulness of detail almost obscured the broader general outlines, but this is inevitable in a work of such an encyclopedic character. Of especial originality and importance is the chapter on what are called residual encephalic lesions. The study of the later stages of hemiplegia contained in this chapter is admirable and is one of the fullest and most detailed contributions to the subject with which we are familiar. An unavoidable delay in the publication of this review enables us to bring stronger testimony to the value of the book as a work of reference from frequent use during the past year, which has shown its completeness and trustworthiness. It takes high rank among the larger treatises on neurology and adds new lustre to the American contributions to the subject.

A Manual of Diseases of the Nervous System. By SIR W. R. GOWERS, M.D., F.R.C.P., F.R.S. Third edition, revised and enlarged. Edited by SIR W. R. GOWERS and JAMES TAYLOR, M.D., F.R.C.P. Vol. I, Diseases of the Nerves and Spinal Cord. Pp. xvi, 692, with 192 illustrations. Philadelphia: P. Blakiston's Son & Co. 1899.

The merits of Sir William Gowers's great work are so widely recognized and they have been so repeatedly praised in these columns that it seems but a work of supererogation to commend this new edition, which has grown to be one-half as large again as the original volume and considerably larger than that of the second edition. A new chapter has been added on the General Constitution of the Nervous System, setting forth briefly the neurone theory. Chapters have also been added on Crural Neuritis, Neuromyostitis, Acute Polymyositis, Herpetic Neuritis, the Family Form of Spastic Paraplegia, Sclerosis from Toxic Blood States and the Family Form of Spinal Muscular Atrophy in Children, and Dr. F. E. Batten has added an appendix on the Muscle Spindle. These, however, represent only a few of the additions, for the whole work has been thoroughly revised, and additions and changes may be found in every chapter, which bring the work up to date. It can therefore be said of this new edition, still more emphatically than we have said before, that it is the best large treatise on nervous diseases extant.

OFFICERS OF BROOKLYN SOCIETY FOR NEUROLOGY. — At the annual meeting of the Brooklyn Society for Neurology, Dr. Wm. Browning was elected President; Dr. R C. F. Coombes, Vice-President, and Dr. W. H. Haynes, Secretary, for the ensuing year.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JANUARY 4, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

OUR ATTITUDE TOWARD INVESTIGATION.

THERE can be little doubt that the new century, and particularly its early years, is likely to witness changes of importance in medical education and matters pertaining thereto. The reforms have, in fact, already begun, and in all progressive institutions we may see, if we look, the introduction of new methods, the extension of the curriculum in various lines, and the gradual complete recognition of the claims of medicine to rank as an integral part of a university education. All these matters we have repeatedly had occasion to allude to in these columns during the past year, but the subject is certainly one which claims our repeated consideration. Evidently many new problems must arise before the new régime may be crystallized into definite and permanent form, if, in fact, that is ever possible, and in the meantime it is desirable to encourage discussion of the situation from all points of view.

We are glad, therefore, to notice that at the recent meeting of the American Society of Naturalists and Affiliated Societies a discussion was held regarding the position universities should take regarding investigation, and that the question of investigation in medicine received its share of attention.

The discussion was opened by Prof. Thomas Dwight, whose remarks we publish in this issue. It will be seen that Dr. Dwight is conservative; that he does not look with undisguised satisfaction on the encroachments of what is ordinarily called original investigation. He feels that the medical student should be a follower rather than an originator during the early years of his education, and that if he is destined later to investigate in new fields, he will surely do so, whatever his early training may have been. There can be no doubt, Dr. Dwight argues, that whatever the future may have in store, the medical school must still make practitioners of medicine, in the practical sense of the term, and that the best schools must not refuse to make the best practitioners. With this we are certainly in complete agreement, only we would not too sharply separate the spirit of learning from the spirit of investigating, as perhaps Dr. Dwight is inclined to do. We feel rather that the two attitudes are usually combined in good students everywhere, and that the great aim of the future, even in undergraduate medical education, must be to associate far more perfectly than we have yet done the claims of the spirit of investigation with those of the spirit of mere receptivity. This should be done in the student days and not after. What we need is a mean between the two extremes of originality and perfectly passive receptivity, and we are confident that a properly arranged course may be devised to bring out both of these attributes to the detriment of neither. To postpone all investigation to an indefinite future is, to our minds, as great an error as to urge its necessity on elementary students to the exclusion of fundamental knowledge at the very outset of their course. A compromise is most certainly both possible and desirable.

We can safely endorse what Dr. Dwight says about prizes and scholarships. As between prizes and scholarships or fellowships, the latter, it seems to us, are likely to be the more useful. There is no way in which a university may more profitably bestow its bounty than by making provision for promising students. A scholarship is a simple means to a perfectly definite end. The indiscriminate bestowal of prizes, on the other hand, establishes an entirely false standard and does little toward stimulating research or cultivating the spirit of true scholarship, an opinion which we have recently expressed.

MEDICAL MEETINGS AND MEDICAL PAPERS.

SOME of us go to medical meetings; some of us write medical papers; a few of us do both, but a large proportion of us do neither. The reasons for these various attitudes of mind are no doubt very complex, and we have no desire to enter upon the task of analysis at this time. We should, however, like to call attention to a few palpable facts, which are constantly in danger of being ignored or forgotten. In the first place, papers which are admirable for publication are oftentimes most unsuitable to read at medical meetings. Medical meetings come usually in the evening; the audience is made up of men who have no doubt been busy during the day, and are hoping against hope that some slight recreation may attend their effort to be present at the meeting in question. They come possibly to learn something new, or to say something in discussion, but they do not come to be bored by detail or kept waiting for conclusions which might as easily be given at the end of fifteen minutes as at the end of an hour. Primarily, therefore, papers should be concise. If the attention of any considerable body of men is to be maintained, it is desirable that it be not taxed beyond half an hour. In this regard we have observed an improvement within the past few years; the tendency has grown at most of our societies to reduce the length of papers by special request to the writers, with a consequent gain in attendance.

Infinitely worse than mere length, however, is redundancy of detail. In certain frames of mind in which, unfortunately, a doctor is very apt to be at the end of a day, details are almost unbearable. They rouse an inward revolt, which bids fair to put the sufferer into the category of the habitual non-attendants. This is due to the fact that minute details are almost never in place at medical meetings, and yet how often we hear them to the absolute confusion of our mental faculties. What idea can it convey to be told the minutiæ of the daily treatment of a patient, temperature in fractions of degrees, pulse, respiration, urine, with its albumin and sugar and urea, and all the shades of change which mark the progress of disease? This is all extremely important as a matter of record, and as the basis of future publication, but as a means of profitable entertainment at a medical meeting it fails most lamentably. To begin with, no one can follow such details; they make no mental impression on the auditors, and even if they did the results are all the audience wants to know. Let the reader state, if he wishes, how assiduously he has studied his case, but let him also prove the effects of his study by giving his matured conclusions on the occasion of his public appearance at the meeting. Such a habit should not be difficult of cultivation, and if universally practised, we have no question the medical meeting would quickly acquire an interest and influence which are now often conspicuously lacking. One other suggestion is the discussion. Why so many words? we frequently wonder. Why weary an already tired audience by an often irrelevant and frequently very long narration of personal experience, which might quite as easily be condensed into a few well-chosen sentences? From many sources a protest has gone up against this bane of the medical meetings. It is becoming more and more the custom to limit the discussion by each speaker to five minutes, with no detriment, we venture to think, to its effectiveness. We need good discussion, but let it be short and to the point. If we could shorten our papers, cut out extraneous detail, and insist on concise discussion, we should no longer be called upon to bewail the proverbially poor attendance at the social and professional gathering which we call a medical meeting.

MEDICAL NOTES.

THREE CENTENARIANS. — Mrs. Mary A. Harrington, of Newport, R. I., died recently at the reputed age of one hundred and three years. On New Year's Day George Washington Greene, a negro, celebrated his one hundred and fourteenth birthday at the almshouse, Hempstead, Long Island, New York, where he has been an inmate for the last forty years. He was born a slave in New Jersey, and the record of his age is said to be authentic. He boasts of having been married seven times and of having been the father of twenty-one children. George Blakeman, the oldest man in Connecticut, died at his home in Derby, December 29th. He was one hundred years and two months of age. He ascribed his longevity to frugal living, and especially to abstinence from all medicine. At the age of twenty-one years he was sickly and completely disheartened after years of medical treatment. It was then that he resolved to eschew all medicine from that time forth. He did so, and his health became robust. He was married for the second time in his eighty-first year.

GOOD HOSPITAL SERVICE.—Sir William MacCormac, who was with the British troops at the recent engagement of the Tugela River, reports that excellent hospital work was done. Trains full of wounded men began leaving the field for Estcourt at two o'clock in the afternoon. Others quickly followed and the field was cleared of the wounded at five o'clock, the volunteer ambulances working splendidly. Eight hundred wounded passed through the Chieveley hospitals, from which all the patients were transferred to the base hospitals by the morning of December 17th, the battle being on the 15th.

SURGEONS FOR THE BOERS.—A report which appears to lack confirmation is to the effect that a hospital ship for the use of the Boers is to be fitted out in America. The plan has originated in Philadelphia, through the agency of the Ancient Order of Hibernians. It has been pertinently asked: What do the Boers want of a hospital ship, since they have no seaboard?

PLAGUE IN HAWAII.—Two cases of supposed plague have been reported from Honolulu. Surgeon-General Wyman, of the Marine-Hospital Service, has notified the authorities at the several Pacific ports, but said that beyond the exercise of extra vigilance no measures would be taken at present regarding the plague, as the situation is not considered critical.

FAMINE IN INDIA.—It is predicted on good authority that the present famine in Western India bids fair to be much more distressing than the famine two years ago. Severe drought has already begun in the Ahmednagar district. In many places it is hard to get sufficient water to drink and no rain may be expected until the middle of June.

ANOTHER CONSULTING SURGEON.—The British War Office has nominated Sir William Stokes as consulting surgeon to the South African forces. He will join the army in South Africa as soon as possible.

DR. THOMAS LAUDER BRUNTON KNIGHTED. — Dr. Thomas Lauder Brunton, physician to St. Bartholomew's Hospital, London, has been knighted.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, January 3, 1900, there were reported to the Board of Health of Boston the following numbers of cases of acute infectious diseases: diphtheria 83, scarlatina 64, measles 57, typhoid fever 6, small-pox 2.

DANGERS OF OVERTRAINING. — This topic has recently been discussed at a meeting, held in New Haven, of the Society of College Gymnasium Directors. Dr. D. A. Sargent, of Harvard, Dr. Edward Hitchcock, of Amherst, Dr. W. G. Anderson, of Yale, and many others spoke. Dr. Anderson, in answer to the query as to the best means of preventing students entering athletic contests when in a crippled condition, strongly favored a scheme such as will probably soon be put into effect at Yale, in appointing a man of wide athletic experience, a college graduate and one in touch with the students, to supervise athletics and to deal with all its questions. There are only two solutions for the question. One is to demand a careful medical examination of the athletes while in training and just before the contest is about to begin. Next there must be hearty co-operation between the medical experts at the gymnasium and the trainer himself. Both must exercise tolerance. This is the solution of the problem under present conditions, which are not ideal.

CONDITIONS IN BROOKLINE, MASS. — The Board of Health of Brookline reports no change in the diphtheria situation. There are still cases at the hospitals, but the outlook for a complete disappearance of the disease is encouraging. Another case of scarlet fever has been reported to the Board. There were three deaths during the month of December.

FREE VACCINATION CEASES IN EAST BOSTON. — Free vaccination in East Boston was discontinued last week, after one week's trial. The number vaccinated was about 500, considerably fewer than had been hoped would accept the opportunity. Two new cases of small-pox have appeared in the district.

ACQUITTAL OF PROFESSOR O. T. OSBORNE. — We are glad to record the acquittal of Dr. O. T. Osborne, of the Yale Medical Faculty, on a charge of performing an autopsy illegally. Charges made by the family of the patient were not sustained by the evidence adduced.

DEATHS FROM WOOD ALCOHOL. — Several deaths have recently occurred at Melrose from drinking wood alcohol; other patients are slowly recovering from its effect.

NEW YORK.

VITAL STATISTICS FOR 1899. — During the year 1899 there were reported in the city 65,218 deaths, 77,648 births, and 30,470 marriages. In 1898 there were 65,864 deaths, 78,696 births, and 28,800 marriages reported. There has been a decrease in the annual death-rate, which was 18.55 in 1898, and 18.37 in 1899; and the percentage of deaths under five years on the total mortality decreased from 38.4 to 36.4. In the Borough of Manhattan the annual death-rate in 1899 was 18.49, against 19.11 in 1898; in the Borough of the Bronx, 22.61, against 27.10; in the Borough of Brooklyn, 17.50, against 18.19; in the Borough of Queens, 18.67, against 19.92; and in the Borough of Richmond, 18.79, against 19.94. It will thus be seen that while the mortality has been lower in Brooklyn than in any other of the boroughs, the greatest decrease in the death-rate has been in the Borough of the Bronx, where the number of large institutions always makes the number of deaths relatively greater than in the other boroughs. The following table, prepared by the Health Department, shows the number of deaths reported in the two years from some of the prominent causes:

Cause of Death.	1898	1899
Influenza	356	481
Measles	648	583
Scarlet fever	703	530
Diphtheria	1,461	1,600
Typhoid fever	670	547
Yellow fever	1	—
Malarial fever	251	161
Cerebrospinal meningitis	355	303
Diarrheal diseases	4,844	3,443
Heart disease	4,075	3,941
Bronchitis	1,896	1,994
Pneumonia	7,485	8,529
Phthisis	7,502	7,991
Bright's disease and nephritis	4,669	5,097
Sunstroke	548	141
Accidents	2,311	2,472
Suicides	693	629
Homicides	115	131
All other causes	26,162	25,826

BILL FOR UNIFICATION OF EDUCATIONAL SYSTEMS. — A bill for presentation to the Legislature has been framed by a special commission appointed by the Governor, which provides for the unification of the educational system of the State and the State Board of Regents. The membership of that body is reduced to fifteen, and the administration of the educational system is placed in the hands of a chancellor, who is to serve for eight years and receive an annual salary of $10,000. At the last meeting of the Board of Regents, Dr. W. H. Watson, of Utica, one of its members, made an argument against the appointment of the chancellor by the Governor, stating that the medical, as well as the legal, profession would be greatly injured by an unworthy choice of the executive head of the proposed Department of Instruction. "The State of New York to-day," he said, "stands in the very vanguard of medical education, and I voice the opinion of all educated men in the medical profession when I state that it considers itself particularly fortunate in having a central educational and administrative body which is at the same time an impartial court (the exact analogue of which exists in no other State) to pass upon the preliminary requirements for medical education and to supervise and conduct the examinations for medical licenses to practise."

DEATH OF FATHER SYLVESTER MALONE. — Brooklyn has lost one of its most picturesque characters and public-spirited citizens in the death of the venerable parish priest, Father Sylvester Malone. His good deeds were not confined to those of his own communion, and when, in 1894, he celebrated his golden jubilee, the fiftieth anniversary of his connection with the Church of St. Peter and St. Paul, a feature of it was a notable reception given him at the Brooklyn Academy of Music, at which the mayor of the city presided and addresses were made by many prominent men,

among them being Rabbi Gottheil, Archbishop Ireland and Dr. Lyman Abbott, the former pastor of Plymouth Church. It is related of Father Malone that he successively contracted small-pox, cholera and ship fever in the performance of his sacred duties among the sick poor and among immigrants, and by his will the bulk of his little fortune of six or seven thousand dollars is left to two charitable institutions in which he was deeply interested.

Tuberculosis in New York State. — A special committee of the State Board of Charities has recently been considering the question of establishing State hospitals for the treatment of tuberculosis. The committee will recommend that every locality able to have a hospital for consumptives should have one, and that the State should erect and maintain one or more hospitals where localities unable to maintain local hospitals might send their patients and pay for their care and maintenance. It will also recommend that local boards of health should have more power in dealing with consumption; that it should be declared to be a contagious disease and that the boards of health should have power to establish rules and regulations to protect from contagion the public and members of families in which the disease exists.

A Public Garbage Crematory. — On December 20th Health Officer Doty had a conference with Governor Roosevelt with reference to the establishment of a public crematory for the disposal of the garbage of the city of New York, which is now managed under private contracts, and it is believed that at the coming session of the Legislature a measure providing for this will be passed. During his recent trip abroad Dr. Doty, acting under instructions from the Governor, inspected the crematories in use for this purpose in a number of the principal European cities, and he arrived at the conclusion that the system employed in Hamburg was the most effective and the best adapted to the needs of New York.

Miscellany.

SPECIAL MEDICINE CHEST FOR THE HOSPITAL SHIP "MAINE."

The following description of a special medicine chest fitted with tabloid and soloid products, for the American Ladies' Hospital Ship *Maine*, deserves such appreciative consideration by our readers as its merits require. This specially designed chest is equipped with medicines in accordance with the latest and most scientific methods.

The chest bears the following designs: On the top panel appear the Union Jack and Stars and Stripes entwined; portraits of George Washington, Queen Victoria and President McKinley; and representations of the American eagle and British lion. The front panel bears portraits of Lady Randolph Churchill (President), Mrs. Ronalds (Hon. Treasurer), and Mrs. Blow (Hon. Secretary of the American Ladies' Hospital Ship Committee); a picture of the hospital ship *Maine;* a scene representing the British lion wounded by an arrow (which lies broken at his side), being administered to by Britannia and Columbia — Columbia pouring a healing balm upon the wound, whilst Britannia bandages the paw. A frieze is formed by a representation of American Indian wampum upon which are depicted Brother Jonathan and John Bull grasping hands. The panel at each end of the chest represents Britannia and Columbia supporting a banner bearing the Red Cross. These panels also contain representations of the national emblems — the English oak and American corn. The panel at the back of the chest depicts a charge of the British Regular and Colonial Lancers and a Highland Brigade. The Boers hold their ground, sheltered behind rocks and boulders. The young bugler boy who felled three Boers is noticeable in the scene. Prominently inscribed on the chest are Keble's line, "No distance breaks the tie of blood," and Ambassador Bayard's notable phrase, "Our kin across the sea." The chest is made of oak and covered with Carthaginian cowhide, upon which the designs are tooled by hand.

AMERICAN SOCIETY OF PHYSIOLOGISTS.

The following scientific papers and demonstrations were presented at the recent meeting of the American Physiological Society at New Haven: T. E. Hough, "Certain Improvements in the Technique of Ergograph Work"; G. P. Clark, "A Model to Represent the Principal Railways of the Nervous System;" S. J. Meltzer, "The Intercerebral Injection of Potassium Chlorate"; C. C. Stewart, "Demonstration of a Method for Mammalian Smooth Muscle"; W. T. Porter, "Apparatus for Laboratory Work for Large Classes"; E. T. Reichert, "Some Forms of Apparatus Used in the Course of Practical Instruction of Physiology in the University of Pennsylvania," and "A Universal Artificial Respiration Device"; L. B. Mendel and H. C. Jackson, "Some Features of Nitrogenous Metabolism after Splenectomy"; P. A. Levene, "Some Basic Decomposition Products of Edestin"; W. J. Giles, "A Preliminary Study of the Coagulable Proteids of Connective Tissues"; L. B. Mendel, "The Excretion of Allantoin and Uric Acid in the Cat."

In the course of the meeting Prof. W. O. Atwater was roused to a defence of his position regarding alcohol, which has of late been the subject of so much superficial criticism. Among other things he said what should long since have been accepted as his view of the matter: "Because these experiments show that alcohol, taken at the rate of two and one-half ounces every twenty-four hours, may serve one of the purposes of food, it has been inferred that people in general may take that amount to advantage. This inference is entirely unwarranted, and the error in it is as great as the opposite one, which assumed that alcohol is in no sense a food, but always a poison. So far from regarding the results of these experiments as showing that the moderate use of alcoholic liquors is generally desirable, I would indorse the saying 'alcohol is an excellent thing for people in good health, and especially for young people, to let alone.'"

The following officers were elected: President, R. H. Chittenden, Yale; Secretary, F. S. Lee, Columbia; Council, R. H. Chittenden, F. S. Lee, H. P. Bowditch, of Harvard, W. H. Howell, of Johns Hopkins, W. P. Porter, of Harvard, W. P. Lombard, of Michigan.

DEATH OF SIR JAMES PAGET.

THE death is reported of Sir James Paget, F.R.C., LL.D., D C.L., former President of the Royal College of Surgeons, England, in his eighty-sixth year. He was born in Yarmouth, Eng., January 11, 1814. He studied at St. Bartholomew's Hospital in London, and in 1836 became a member, and in 1843 a fellow, of the Royal College of Surgeons. He was then made successively assistant surgeon, surgeon and consulting surgeon at St. Bartholomew's, sergeant-surgeon to the Queen, surgeon to the Prince of Wales, vice-chancellor to the University of London, and president of the Royal College of Surgeons. He was made a baronet in 1871. In his earliest surgical studies he paid special attention to pathology, and for years his "Lectures on Surgical Pathology" was a text-book of importance.

Correspondence.

HOMEOPATHY AND THE PUBLIC.

CONCORD, N.H., December 29, 1899.

MR. EDITOR:—That the medical practice of to-day presents features greatly modified from those which characterized it in the recent past is frequently a subject of remark and a source of congratulation as well. These changes are manifest upon every side where one comes in contact with the healing art. One need not recall many years of the past to find medicine the victim of mischievous theories, burdened by gross materialism and barbarous in its methods of application. The consequences were a system of heroic treatment and a long-suffering public. Those fittest to survive were truly heroes—men with limb of iron and heart of oak. One of these modifications may be seen in the intellectual quality of those that now represent the medical profession. In medieval times the physician was generally a slave, whose only medical knowledge consisted in a belief in the supernatural influence of charms and amulets. In more recent times the student with meagre education was prepared for professional life by pursuing a course of instruction under the guidance of an older practitioner, which was supplemented by a few weeks' course at a medical college. The traditions of practice were passed along from preceptor to student, the orthodox spirit of the times forbidding any departure from established custom. To-day a satisfactory preliminary education of a scientific nature is required of the student for entrance to medical schools, which are being graded to the four years' course throughout the country. The present intellectual freedom of the members of the profession is leading to discoveries which are placing medicine upon a scientific foundation.

There are also apparent agreeable changes in the armamentarium of the art and methods of treating the sick. Enormous doses and complexity of mixtures have largely disappeared relieving humanity of much distress on their account. Saddle bags and medicine trunks have given way to the pocket medicine case containing vials of simple medicines.

The apothecary store has undergone a change, and is but the dispensary of what the pharmaceutical house prepares with skill and accuracy. At the present time the preparation of drugs in elegant and agreeable forms for administration has reached an art in itself.

Various influences have been active in the transformation of the external features of medicine and are found to have been operative both from without and from within. Medicine has been profoundly influenced by its environment. It has gradually felt the resistless force of the scientific spirit prevailing in other fields of research with which it is intimately associated. This has led to closer observation and clearer comprehension of natural phenomena, with a more rational interpretation of pathological phenomena and treatment. Putting it another way, it may be said that the critical acumen that pervades all departments of thought has found much in medicine to relegate to effete and outgrown custom, regardless of ancient authority, thus clearing the path for progress towards a rational standard in therapeutics. The external form of past methods of alleviating the afflicted are open to criticism, but the object of the conscientious physician has ever been the serving of his patrons to the best of his knowledge. Medicine is to-day altruistic in principle, and as a result of increased knowledge and a keener sense of obligation to a higher standard its theories are more rational and its methods of treatment more humane.

This is now the place to mention another influence which at the beginning was as insignificant as a grain of mustard seed, but which has since produced a distinct modification in general medicine along a certain line. At the beginning of the present century there appeared within the field of medicine, but not accepted as a part of it by the members of the profession, the system of treatment known as homeopathy. The contrast between the new system and the established régime was the widest possible, not so much in its claim of having discovered the only law of cure of nature, for other systems of the times had such dominant theories, as in its methods of applying its theories in practice. Its administration of medicine involved so little material and was withal such a simple method that the apothecaries and physicians, fearing for their livelihood, combined in vigorous opposition against the innovation that lessened the large consumption of drugs and correspondingly endangered their income.

Conservatism has always been the spirit of so-called traditional medicine. It has not mattered whether an innovation contained the truth or was mistaken in its claims, the attitude of the profession at first has been sure to be antagonistic. Those great discoveries of the past which illumine medicine to-day ran the gauntlet of prejudice and ignorance on the part of the profession and found their champions in the common people. The profession as a whole has been the last to esteem the value of its own findings. At least, this is what happened to homeopathy, for the new system won the public readily. There was something in this new method that the public wanted, and so persistently has the public clung to it that it has actually forced the old systems to change, so that to-day there is so little difference in the external appearances of things that one can scarcely distinguish between the different systems of treatment. This leavening of the whole mass has been due to something contained in the new system. We will endeavor to find the ferment that has been so potent.

From a philosophical standpoint the distinguishing characteristics of a system lie in its dogmas. The pivotal theory of homeopathy is its claim of having nature's law of cure as expressed in the symbol, *similia similibus curantur*, or, like cures like. This simply means that there exists naturally a therapeutic relation between the abnormal condition resulting from a morbific cause and the most similar abnormal condition that a drug is capable of producing, which is its characteristic physiological action. The drug disease takes the place of the natural disease, and in turn is easily overcome by the vital powers of the body. It is further claimed that this can best be accomplished by a very small dose. The question now arises as to whether it has been the force following a clear conception of this central dogma by the public that accounts for the establishment and influence of homeopathy.

The principle of homeopathy has failed of a general acceptance, as such, among scientific men. They have been unable to associate its claims of a natural law with other laws of nature. Two of the characteristics of a natural law are its infallibility and its universality. These were the claims of the early homeopaths, whose zeal led them into extravagance of belief. The present conception of the principle of "similia" as being of therapeutic value

in a certain proportion of cases may be the truth of the whole matter, but this allows the claim of "a law of nature" to pass into "innocuous desuetude," where it will forever remain.

From the so-called regular profession homeopathy has met the fiercest opposition. Raising the cry of "no sects, no dogma in medicine," the opposition has spitefully arrayed its ranks against the new system in all it contained. At no time in the past — the same is less true of the present — have those most vigorous in denunciation of the new system been those really able to define its law correctly and caring to investigate its claims impartially. It has not been its central theory that has made its enemies. As compared with the standard set by the fathers of homeopathy the present practitioners of this system are a "mongrel lot," inasmuch as they make use of the name homeopathy and all it implies, publicly, and privately confess that they find the claim of universality a fallacious doctrine. After a recent investigation by correspondence with a large number of homeopathic physicians, graduated within the past ten years, I find that the large majority consider homeopathy as one of many methods of cure, the idea of its being a "law of nature" not being taken seriously.

Homeopathy has found its moral and financial support in public sanction. The writer, having been a practitioner of this system for the first five years of his professional life, has given the subject in hand a large amount of thought and investigation, and has definitely come to the conclusion that the public possess no clear, if any, conception of the philosophy of the system they have patronized so generously. Confidence and faith are naturally the qualities displayed in such matters rather than an intelligent appreciation of a mystic dogma. It has not been its central theory that has made its friends. We must look to some other element in the system in order to account for its public reception and support.

The objective and most tangible feature of homeopathy is its dose. This is its outward expression. If the public failed to comprehend the theory, it found in the small and simple dose a more humane and agreeable method of treatment than that which employed enormous doses of complex mixtures. Wherever homeopathy is referred to, in journalism, pulpit or lecture, it is its infinitesimal dose that is mentioned. The definition of the public is that homeopathy is "a little medicine given often," and this is what they like about it. The small dose in years past has been the point ridiculed by the ignorant of the regular profession, but it is now being considered as rational and scientific to employ the small and simple dose. Thus with popular approval and with a scientific foundation the small dose of homeopathy has been an active agent in the field of therapeutics. This is but another example of the kernel of truth being hidden in the husk of error.

Homeopathy was the product of the eighteenth century. This was an age when men were striving after complete theoretical systems in medicine. Among the celebrities of this time may be mentioned Hoffman, Stahl, Cullen and Brown, each with a theoretical system. At the close of the century appeared Hahnemann with the system of homeopathy. His was to him the true system of all systems because of its universal law of cure, *similia similibus curantur*. But the true superiority was the employment of his idea of the small dose, which has been a positive contribution to therapeutics.

In conclusion, it is the contention of the writer that it has been the small dose rather than, and apart from, the homeopathic law that has appealed to the public; that the public has demanded of other methods the small dose which lies upon a rational foundation. It is further contended that the medicine of the future will rest upon scientific rather than upon theoretical grounds, as is the case with the homeopathic system. The public has chosen between the old and the new because of the agreeable dose apparent in the latter. When all schools of medicine shall have reached the point where the manner of administering medicine is the same, as far as the public can judge, there will be nothing to choose. All doctors will be known as physicians; useless controversy about schools in the profession will cease, and homeopathy will, "like a dew drop glide into the shining sea." The dose will have leavened the lump.

Very truly yours,
ARTHUR F. SUMNER, M.D.

X-RAY EXAMINATIONS OF THE ABDOMEN.

BOSTON, December 30, 1899.

MR. EDITOR: In previous articles I have indicated the diseases of the chest in which x-ray examinations may assist physicians, in addition to the usual methods. The older ways of examining the abdomen may also be supplemented by x-ray examinations, as I have already shown, but I think it would be helpful to again remind practitioners of some of the principles involved in making examinations of this part of the body, which are as follows:

We may put something opaque to the rays into the hollow organs, such as the stomach and intestines, thus making dark areas on the fluorescent screen, or we may put into them something which offers practically no obstacle to the rays, namely, air or some other gas, thus making their position apparent; the parts so distended appear as light areas on the fluorescent screen. Or, further, we may use air or gas to displace the parts near some special organ which we wish to examine. Thus, if we desire to follow the outline of the spleen more fully, we can, by filling the stomach and large intestine with air, contrast the dark area of the spleen with the light area occupied by the gas, through which the rays readily pass.

When it is desired to examine the large intestine, air may be pumped into it, and its outline, such as the sigmoid flexure, and the descending colon, be easily followed. Not only does this enable us to follow the position occupied by the large intestine, but we may more readily detect abnormal conditions in neighboring parts of the abdominal cavity, as I have elsewhere suggested. For example, by distending the stomach, and in some cases the large intestine, we can more easily detect some pathological conditions in or about the pancreas.

Examinations of the abdomen should be made with the rays passing through the body from back to front and from side to side; and when fluid is present the examination should be made with the patient lying on his back and the tube on a level with the fluid, the rays from it passing through the abdomen horizontally. The dark line indicating the level of the fluid may be seen, and its change in position noted when the patient turns. Patients with so-called "phantom tumor" should of course always be examined by the x-rays.

It will thus be seen that the same conditions which obtain in the thorax, and which enable us to contrast the air in the lungs with the denser organs, may to some extent be produced artificially in the abdominal cavity.

In this connection it will be of interest to note the following observation, which suggests that food may be passed nearly the whole length of the intestines within a few hours. I gave six drachms of subnitrate of bismuth, mixed in bread and milk, and drew the outlines of the stomach as seen on the fluorescent screen at intervals during the process of digestion. X-ray photographs were also taken. Five and one-half hours after the bismuth had been given (on an empty stomach), it had collected on what I considered to be the position of the sigmoid flexure, as shown by a dark mass there which had not been present in the beginning; thus the bismuth had gone nearly the full length of the intestines in less than five and one-half hours.

Of course, it facilitates examinations of the abdomen if the bowels are moved well before the examination is made; and bismuth should be taken on an empty stomach and uniformly mixed with the food.

Very truly yours,
FRANCIS H. WILLIAMS, M.D.

METEOROLOGICAL RECORD

For the week ending December 23d, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 2,762; under five years of age 842; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping-cough, erysipelas and fevers) 277, acute lung diseases 516, consumption 314, diphtheria and croup 130, typhoid fever 37, diarrheal diseases 29, scarlet fever 25, measles 22, whooping-cough 12, erysipelas 11, cerebrospinal meningitis 11.

From scarlet fever New York 10, Boston 6, Philadelphia 5, Pittsburg, Providence, Fall River and Haverhill 1 each. From measles New York 15, Providence 3, Pittsburg 2, Philadelphia and Fall River 1 each. From whooping-cough New York 8, Washington, Providences, Lynn and Chelsea 1 each. From erysipelas New York 8, Boston, Pittsburg and Holyoke 1 each. From cerebrospinal meningitis New York 6, Philadelphia 2, Worcester, Lynn and Lawrence 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,404,408, for the week ending December 9th, the death-rate was 20.8. Deaths reported 4,551: acute diseases of the respiratory organs (London) 548, measles 135, diphtheria 113, fever 75, whooping-cough 70, scarlet fever 38, diarrhea 38, small-pox (Hull) 11.

The death-rates ranged from 13.1 in Croydon to 26.4 in Plymouth: Birmingham 16 9, Bradford 19.9, Cardiff 14.3, Gateshead 21.5, Hull 23.4, Leeds 18.2, Leicester 21.0, Liverpool 25.9, London 22.4, Manchester 20.8, Newcastle-on-Tyne 11.0, Nottingham 14.4, Salford 21.7, Swansea 20.1, West Ham 16.5.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,404,408, for the week ending December 16th, the death-rate was 22 0. Deaths reported 4,820; acute diseases of the respiratory organs (London) 646, measles 143, diphtheria 124, whooping-cough 86, fever 49, diarrhea 48, scarlet fever 38, small-pox (Hull 12, London 1) 14.

The death-rates ranged from 9.6 in Huddersfield to 30.3 in Portsmouth; Birmingham 22.6, Bradford 20.5, Cardiff 19.9, Gateshead 16.1, Hull 22.3, Leeds 20.4, Leicester 22.7, Liverpool 26 5, London 23 8, Manchester 18.8, Newcastle-on-Tyne 19.4, Nottingham 19.4, Salford 23.4, Sheffield 21.4, Swansea 24.6.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING DECEMBER 30, 1899.

H. E. AMES, surgeon, order of December 20th modified; ordered to duty in connection with fitting out the "Kearsarge," Newport News, Va.

E. J. GROW, assistant surgeon, detached from the "Massachusetts" and ordered to the "Dixie."

M. H. SIMONS, medical inspector, ordered to Cleveland, O., for recruiting duty.

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.— The annual meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday evening, January 8th, at 8 o'clock.

Subject: "Treatment of Perforation of the Intestines in Typhoid Fever." The discussion will be opened by Dr. Geo. B. Shattuck, to be followed by reports of cases.

Election of officers.

ARTHUR K. STONE, M.D., *Secretary*, 657 Boylston Street.

RECENT DEATHS.

SIR JAMES PAGET, M.M.S.S., Hon., died in London, Eng., December 30, 1899, aged eighty-five years.

GUSTAVUS STORRS WINSTON, M.D., of New York, died on December 29th, of apoplexy. He was born in New York City, November 15, 1833, and was graduated from the College of Physicians and Surgeons, Medical Department of Columbia University, in 1863. He was a surgeon in the army during the Civil War and, being captured, was confined for a time in Libby Prison. At the time of his death Dr. Winston was medical director of the Mutual Life Insurance Company, of which his father, the late Frederick S. Winston, was formerly president.

THOMAS O'CALLAGHAN, M.D., one of the oldest and best-known practitioners of Jersey City, N. J., died suddenly of apoplexy on December 27th. He was born in Ireland in 1831, and was graduated from the College of Physicians and Surgeons, New York, in 1860.

BOOKS AND PAMPHLETS RECEIVED.

A CASE OF PERFORATING GASTRIC ULCER; OPERATION; RECOVERY; WITH REMARKS ON THE SURGERY OF GASTRIC ULCER.[1]

BY F. B. LUND, M.D., BOSTON.

W. L., thirty years old, married, a laborer by occupation, was sent to the Boston City Hospital by Dr. J. H. Gavin, of Roxbury, on the evening of June 20, 1899, for operation for general peritonitis. He was admitted to the service of Dr. Abner Post, in whose absence the writer saw the case. His history was as follows: For a year or more he had suffered from indigestion, manifested chiefly by flatulency, eructations, and a dull heavy pain in the epigastrium, the sensation resembling that of a "load on the stomach," as he expressed it. There had been vomiting on rare occasions. For the last two months he had been taking care of one of his children, who had died of some thoracic trouble two days ago, and he had become exhausted. Last evening he had taken one glass of whiskey and one of beer, and had vomited, but his acute symptoms had not begun till 8 A. M. on the day of entrance, when he was seized with agonizing pain in the epigastrium, and vomited several times. The pain had continued without abatement all day, but there had been no more vomiting. He had taken no food during the day.

He was seen by the writer at 12 P. M., or sixteen hours after the attack of pain which undoubtedly signalized the perforation. At that time he looked pale and anxious. His tongue was dry and coated dark brown. He had tenderness and muscular spasm all over the abdomen, especially marked in the epigastrium. The pulse was 100 and strong, and the temperature normal. There was no abdominal distention, in fact the abdomen was retracted, but universal tympanites. The diagnosis was made of general peritonitis, probably originating in the epigastric region, perforating gastric or duodenal ulcer and acute pancreatitis being thought of, as well as appendicitis.

Under ether, after the usual preparations, an incision was made into the abdomen in the middle line above the umbilicus. On opening the peritoneum there was immediate escape of gas and light green-colored stomach contents. The incision was immediately prolonged till it extended from the ensiform cartilage to below the umbilicus. The anterior surface of the stomach and the small intestine were covered with a thin layer of fibrin, and as the flow of gastric fluid seemed to come from the pyloric region, a short cross incision was made and the wound retracted forcibly to the right, exposing a clean-cut ulcer about three-eighths of an inch in diameter on the anterior surface of the stomach, three-fourths of an inch to the left of the pylorus. The stomach above the ulcer was held by the thumb and forefinger of an assistant to prevent further escape of gastric contents, and by strong retraction of the wound toward the right sufficient space was gained to fold the ulcer in, the fold being arranged at right angles to the axis of the stomach, in order to prevent cicatricial contraction, and held by three rows of Lembert sutures of fine silk. As the first row could not be placed close to the ulcer on account of the friability of the infiltrated stomach wall, it was necessary really to fold the pyloric portion of the stomach over onto the first portion of the duodenum. Before suture the field of operation was washed with sterile salt solution and wiped dry, and the rest of the abdomen walled off with gauze.

After completion of the suture, another incision one inch long was made half-way between the umbilicus and symphysis pubis to drain the pelvis. The abdomen was washed out with hot sterile salt solution. There was a general peritonitis, the peritoneal covering of small intestines being inflamed and flakes of fibrin attached. Pus and fibrin flakes were found in pelvis and both lumbar regions. After thoroughly washing with salt solution, the pelvis was drained with three gauze strips and a glass tube. Through the upper wound a gauze drain was passed to the line of sutures and into the right and left lumbar regions. The wound was partially closed by sutures around the strips. Two ounces of Epsom salts were injected into the jejunum through a hollow needle, and the puncture closed by a suture. The patient bore the operation well and did not vomit on recovery from ether. In fact, he never vomited after the operation.

The treatment consisted of enemata of salt solution with brandy and strychnine during the first twelve hours, and after that, of nutrient enemata of peptonized milk, egg and brandy.

The bowels moved on the morning following the operation, but the man's condition was serious, as he was restless and weak, with rapid (130) and intermittent pulse. A little tincture of digitalis was added to the enemata, and the restlessness was markedly improved by morphine. The next day the pulse fell to 90, and from that time on his improvement was rapid and continuous. He was given hot water by mouth on the third day, and the gauze packing removed on the fourth day. Beef juice, beef tea and milk and lime-water by mouth were begun on the eighth day, and were well borne.

Sixteen days after the operation the rectal feeding was discontinued. Solid food was begun one month after the operation. The patient gained rapidly in weight and strength, and left the hospital on August 14th in excellent condition, with a small sinus discharging very slightly. This sinus, the persistence of which was the reason for keeping the patient in the hospital so long, healed within two weeks of his leaving, and he is now entirely well, and weighs more than he did when he left the hospital. He is entirely free from digestive disturbance. A culture taken at the time of the operation showed the presence of the streptococcus pyogenes and the bacillus coli communis in the peritoneal fluid.

The fortunate recovery in this case, although the operation was performed sixteen hours after the perforation, which, in my opinion, took place immediately with the onset of pain and vomiting at eight o'clock in the morning, may have been partially due to the fact that at the time the perforation took place there were no solid contents present in the stomach, as the patient had taken no food that morning, and the stomach had been presumably emptied by the vomiting which took place the evening before.

The location of the ulcer on the anterior surface was favorable to suture. The procedure adopted of folding in the ulcer, instead of attempting to excise the edges, seems to me distinctly the most satisfactory method in these cases. Excision would mean addi-

[1] Read before the Surgical Section of the Suffolk District Medical Society, November 1, 1899.

tional operative manipulation, management of hemorrhage, etc., which should certainly be avoided on account of the danger of spreading sepsis, in the presence of extravasated gastric contents, peritoneal exudate and pus. The patient's condition in general in these cases contraindicates indulgence in any technique which is more elaborate than essential. In placing the sutures it is well, when possible, to begin farther from the edge of the ulcer than one thinks is necessary, for the tissues are infiltrated to a wide extent, and the sutures will not hold unless passed through healthy tissues. Fine silk is the best suture material.

In regard to the importance of thorough irrigation and drainage of the peritoneum, I need add nothing to the views already expressed in my paper on general peritonitis a year ago.[3] The injection of saturated solution of Epsom salts into the bowel has in my hands had the happiest results, in producing an early movement of the bowels, and in those cases which have not immediately died of shock and sepsis the convalescence has seemed to me distinctly smoother and more comfortable than in the cases where it has to be omitted. Although not essential to success, as is the case with irrigation and drainage, it seems to me a distinct advance in treatment, and one which in a doubtful case may turn the scale in the patient's favor. It is especially important in cases which have gone on till the bowels are distended with flatus, although, unfortunately, cases of general peritonitis which have gone on till marked distention of the bowels has resulted are less apt to yield to treatment. In this case, although the presence of seropus and fibrin flakes universally over the small intestine showed that the peritonitis was indubitably general, the bowels had not become distended with gas and were empty and flat. Nor had the septic intoxication sent the pulse up to an alarming extent or greatly depressed the patient's general condition, all of which factors were favorable to his recovery. These facts emphasize the necessity of *early* diagnosis and immediate operation.

In looking up the subject of operation for perforating gastric ulcer, I have been surprised and gratified at the favorable showing made by recent statistics.

Statistics on such a subject as this without doubt give a more favorable showing than is actually the case, owing to the fact that there is little doubt that more fatal than successful cases go unreported. None the less, the improvement in results in recent years, due doubtless both to early diagnosis and improved technique, is extremely encouraging. Richardson, in Dennis's "System of Surgery," in 1894, collected 43 operations for perforating gastric ulcer, with 10 recoveries, or 23 per cent. Dr. Farrar Cobb has kindly placed at my disposal a table of cases subsequent to Dennis's table and carrying the time up to the spring of 1897. This table includes 98 cases, with 50 recoveries, or 51 per cent. Adding these two lists together gives 141 cases, with 60 recoveries, or 42 per cent. Now of these 141 cases, 45 were operated within twelve hours, with 35 recoveries, or 78 per cent., and 70 within 24 hours, with 44 recoveries, or 63 per cent.

I have since myself collected 40 additional cases, with 28 recoveries, or 70 per cent. Of these, 14 were operated within twelve hours, with 12 recoveries, or 86 per cent., and 26 within twenty-four hours, with 19 recoveries, or 73 per cent. Now, adding all the cases, we have the following result:

	Cases.	Recoveries.
Dennis (to 1894)	43	10 = 23 per cent.
Cobb (to 1897)	98	50 = 51 per cent.
Author (1897 to date)	40	28 = 70 per cent.
Total	181	88 = 45 per cent.

The improvement in these statistics with time, the progression from 1894 to 1899 being 23, 51, 70 per cent., is remarkable. Now, adding together those operated within twelve hours, we have:

	Cases.	Recoveries.
Dennis and Cobb	45	35 = 78 per cent.
Author	14	12 = 86 per cent.
Total	59	47 = 79 per cent.

Operated within 24 hours we have:

	Cases.	Recoveries.
Dennis and Cobb	70	49 = 63 per cent.
Author	26	19 = 73 per cent.
Total	96	63 = 65 per cent.

The results of published operations, therefore, show a surprisingly high recovery rate.

On examining the records of cases operated on days and weeks after perforation, we find an occasional recovery. This is due to the fact that perforation, whether the ulcer is on the anterior or posterior surface of the stomach, takes place not infrequently into a cavity walled off by adhesions, so that localized abscesses, subphrenic, perisplenic, etc., result, which are finally opened and drained, with an occasional recovery.

The history of these cases, however, is one of continued suppuration, exhaustion and emaciation, and not infrequently death, even after operation for drainage of the abscess with perhaps suture of the stomach. These abscesses have occasionally perforated the diaphragm and produced empyema, or even ruptured into a bronchus.

In cases where perforation takes place into the general peritoneal cavity immediate operation is essential to save life. In cases where the spread of pus is limited by adhesions operation at the earliest possible moment is indicated to prevent the gradual extension of the suppurative process, exhaustion and sepsis. Of 187 cases of gastric ulcer (Elliot and Joslin) treated at the Massachusetts General Hospital between 1888 and 1898 perforation took place in six, or 3.2 per cent., and was fatal immediately or ultimately in every case.

Since collecting the above statistics I have found a monograph by M. B. Tinker, now assistant to Dr. Keen, of Philadelphia, entitled "Die perforiende Magengeschwüre und ihre chirurgische Behandlung," being his Inaugural Dissertation for the Doctorate in Medicine and Surgery presented at the University of Berlin in July, 1899.

This paper is based upon an analysis of 213 cases, which have been collected from literature, and covers the subject thoroughly up to the present time. It is certainly the most thorough and complete presentation of the subject which I have seen, and it is gratifying to note that the results of his tabulation correspond closely with my own.

He tabulates 78 cases collected by Weir and Foote,[5] 78 cases tabulated by Keen, Cartwright Lectures,[4]

[3] Boston Medical and Surgical Journal, 1898, cxxxix, No. 10.

[5] New York Medical News, 1898, xviii, 49.

[4] Philadelphia Medical Journal, May 7, 1898.

and 57 cases collected by him from literature since that time, a total of 213 cases. The average mortality was 48.81 per cent. The mortality of Weir and Foote, 78 cases (previous to 1896), was 71, 51 per cent., while the mortality of the cases since 1896, 112 in number, was only 35 per cent. In the last three years, since 1896, of the cases operated within twelve hours, 16 in number, only three died, a recovery percentage of 82.36, which agrees closely with my own tabulation. For the analysis as to age, sex, situation of the ulcer and other important and interesting divisions of the subject, the reader is referred to the original paper. An interesting geographical table must be mentioned here, however, which shows that of the 213 cases, 142 were operated in England and her colonies. Germany contributed 26, the United States, 18, and France, 17. The first operation was performed by Mikulicz in 1880, and the first successful operation by Kriege in 1892.

While there can be no question of the absolute necessity of operating upon cases of perforating gastric ulcer at the earliest possible moment, there has lately been a somewhat remarkable accumulation of evidence to show that surgical aid should not be withheld from certain other cases of gastric ulcer which have heretofore been largely regarded as amenable only to medical treatment. The operations of pyloroplasty in cases of contraction of the pylorus from the contraction of the scars resulting from benign ulcer, of gastro-enterostomy or excision in cases of repeated and dangerous hemorrhage, or of continued vomiting unaffected by treatment, should, I believe, in the light of the perfection of modern technique, and of the unfavorable showing of recent statistics relating to the medical treatment of these cases, be oftener performed than they are at present.

The mortality of gastric ulcer has been estimated at from two to eight per cent. and the percentage of complete cases is given at from 85 per cent. by Welch, based on the result of autopsies, to 75 per cent., Ewald and Leube, and 50 per cent., Debove and Remond. But the figures given as the result of clinical investigation do not give a fair estimate of the number of cases, for the reason that no account is taken of the relapses which follow after the patients have passed from under observation.

Of especial interest in this connection are the results of the extremely valuable investigations of Greenough and Joslin,[5] into the condition of 114 cases of gastric ulcer at an average period of five years after their discharge from the Massachusetts General Hospital. The difficulty of following up hospital patients is so great that investigations such as this are rarely carried out, and the information derived from them is especially important. Of 187 patients treated at that hospital between 1888 and 1898, reports of the condition of 114 of these were obtained at an average time of five years after their discharge.

To quote from this paper, of 114 patients, 80 per cent. were discharged cured or relieved, but at the end of an average period of five years only 40 per cent. remained well. The mortality at the same time was 20 per cent. The mortality of eight per cent. and the failure of medical treatment to effect a lasting cure in 60 per cent. of the patients indicate the need of surgical intervention in other than emergency cases.

Surgical intervention in cases of hemorrhage has been objected to on the ground that the operation had a high mortality, about 61 per cent., while the majority of cases in which hemorrhage occurs are not fatal, as in fact hemorrhage is a symptom in about 80 per cent. of all cases. The mortality of operations for hemorrhage has been necessarily high because the operation has been performed as a last resort after grave anemia had been produced, and, in fact, often on moribund patients.

Although the majority of cases of hemorrhage from gastric ulcer do not require surgical intervention, we have every reason to believe that in cases of small and frequently repeated hemorrhage inducing grave anemia, or in severe and copious hemorrhage, lives might be saved if surgical aid were invoked before grave anemia threatened imminent death. Surgical aid in gastric hemorrhage, as in other abdominal emergencies, must be summoned early, in order to be effective in saving life. Into the various operative procedures applicable in hemorrhage it is not the purpose of this paper to enter in detail. Suffice it to say that excision of the ulcer, cauterization and gastro-enterostomy may be practised; the choice of operation must be made at the time, according to circumstances, situation of ulcer, size and position of artery, condition of patient, etc.

Another class of cases which should, in my opinion, be more often given the benefit of surgical treatment are those in which severe pain and vomiting continue unaffected by medical treatment, and in which progressive emaciation results. In these cases the more extensive and indurated ulcers, frequently attended with contraction of the pylorus and gastric dilatation, will have to be dealt with. Pyloroplasty, excision of the ulcer and gastro-enterostomy will here be the operations to be considered.

The mortality of gastro-enterostomy has diminished considerably within the last few years. Cutler and Elliot have estimated it at 30 per cent., and Mikulicz at 16 per cent. Bidwell[6] has collected 63 cases operated upon in the last two years, with a mortality of 64 per cent., which is certainly a remarkable reduction. With earlier resort to operation and greater familiarity with the technique on the part of surgeons, there is no reason why the mortality of operations for gastric ulcer should not diminish as remarkably as has that for appendicitis.

In operations for non-perforating ulcer we are not dealing with infected peritoneum, and modern technique and the use of gauze packing have enabled those skilled in abdominal surgery to perform extensive intestinal resections and the like with little fear of general peritoneal infection.

Operations on the stomach are not intrinsically more difficult than those upon the intestine; the greater part of the posterior wall of the stomach even can be brought outside the abdomen and operated upon extraperitoneally. The thick walls of the stomach afford better holding ground for sutures than the walls of the intestine.

If the operations for perforated gastric ulcer which are done within twelve hours of perforation show so surprisingly low a mortality, even in the presence of infected peritoneum, may we not hope to attain highly

THE CASE METHOD OF TEACHING SYSTEMATIC MEDICINE.

BY W. B. CANNON, A.M., BOSTON,
Student, Harvard Medical School.

THE articles on methods of medical instruction recently published and the widespread interest aroused by the papers are the surface showings of an agitation at present deeply affecting the best medical schools throughout the country. Among many instructors there is manifest dissatisfaction with the traditional means of training physicians, a dissatisfaction rising apparently from the belief that the teaching of medicine has not been keeping pace with improvements in the teaching of other subjects. Discussion of old methods and earnest searching after new and more effective methods of preparing young men to be practitioners are consequently rife amongst us. The medical student catches the spirit of this agitation and notices features of his education which seem to him capable of improvement. From a student's point of view, therefore, the present paper on the teaching of systematic medicine is offered.

That clinical instruction alone is too haphazard and uncertain to form a basis for a complete and orderly course in medicine is recognized in most medical schools. The well-rounded preparation for practice which the student must receive demands, therefore, aside from the clinics, an organized course of study. With this conclusion, that more systematic instruction is needed than clinical material can afford, this paper is in agreement; the method by which such systematic instruction is given, however, it proposes to discuss.

Two general methods of teaching systematic medicine have hitherto prevailed, namely, by the didactic lecture, and by recitations on stated topics. Strong objections can be raised both to didactic lectures and to recitations as used in teaching medicine; but the methods have, as well, certain valuable features demanding respect. Manifestly, any alternative for these methods which will avoid their defects and include their merits will be doubly valuable. That the case method of instruction offers such an alternative for the prevalent teaching, it is the purpose of this paper to show.

Before the didactic lecture and the recitation system are considered more in detail, it will be well to have clearly in mind the nature of medical practice and the consequent requisites of medical training. Medical practice is an art, an application of accumulated knowledge and skill to a particular case. It has two aspects: that of observation, and that of interpretation and relief. The first aspect — that of observation — requires of the physician sharp insight in questioning his patient, skill in making a thorough physical examination, and shrewdness in judging human nature. The preparation for this side of the physician's work is preeminently clinical; the best training for the examination of the sick is actual practice in such examination by the student under the supervision of an instructor. Observation gives data. Now these data must be explained and in accordance with this explanation the patient must be rightly treated. In this second attitude as interpreter and helper, the physician brings to bear on the patient the heritage of the past of medicine in so far as this heritage explains the nature of the sickness, as a disturbance of normal structure and function, and provides principles for diagnosis, prognosis and rational treatment. In short, a doctor's work consists in examining disordered individuals, and in applying to them the judgment of a trained mind and a careful knowledge of previous art. If these trite statements need apology it is found in the desire for perfect clearness in the argument which follows. In this argument only the preparation for the second of the attitudes of the physician will be considered, namely, the education of his reason as an interpreter, and the provision of his knowledge as a helper. And first of all the question arises: Is the didactic lecture the most satisfactory and effectual method of drilling the mind to careful thought in diagnosis and prognosis, and of securing to the student definite and ready knowledge of accepted practice?

Among the objections to didactic lectures as a means of instructing the student of medicine, perhaps the least important is the contention that attendance on such lectures is not an economical use of the student's time. This objection, however, is more important in these days of the crowded curriculum than formerly, and is sure to become still more important as, with the advance of medicine, the demand on the student's time increases. The chief support of the objection lies in the fact that lectures on medical subjects present, in the main, only what can be found in the newest textbook. Now, in case the student does not take notes he sits as a passive listener. It is well within the bounds of certainty to affirm that the many points made every week in ten or fifteen lectures on different subjects cannot be fixed permanently in memory by hearing them stated only once. If this student makes up his deficiency, however, by reading his authorities, he is doing precisely what he might quite as well have done without spending time listening to lectures. But suppose the student takes notes of what he hears. Then, according to common testimony, he is so busy writing he learns at the time very little of the matter presented by the lecturer. The student, therefore, is merely accumulating reading matter, and of this he already has as much as he can well manage. Furthermore, he not unfrequently finds that his own inability or the lecturer's obscurity has resulted in notes not good enough to trust. In this instance, likewise, he must depend upon his books. The conclusion seems justified, therefore, that the student, driven to the textbook in spite of didactic lectures, will make better use of his hours by learning systematic medicine directly from the printed sources.

A more serious criticism can be brought against the lecture system in that it allows a slighting of study during a large part of the year and favors cramming for examinations at the end. Some instructors, indeed, seem to regard this condition as essential, and leave time in May for preparation for June examinations. And the students, as well, count on this cramming, for many of them stop attending clinical exercises in May, in order to study their accumulated notes for satisfactory grades. The ephemeral nature of knowledge gained under such circumstances is too well known to need emphasis. It does not become an organized and

convenient part of the physician's equipment; and in so far as the lecture system respects the examination paper, rather than the permanent and handy store of information, the grave charge of inadequacy can be brought against it.

By far the most important and most weighty objection to the lecture system, however, is its real inefficiency as a means of mental training for medical work. Since medicine is an art, the doctor's relation to his patient, as every one knows, is an *active* relation. It requires therefore not only a ready fund of information, but also a disciplined power of careful observation and thoughtful analysis. Now, the ability to practice an art well requires, as every one knows also, preliminary training in that very practice. Manual dexterity is not learned by hearing about it, nor does skill in debate come from reading descriptions. Why, then, should medical students be expected to reason clearly in medical matters, weigh conflicting evidence or draw just conclusions, when their chief practice is taking lecture notes? The passive attitude of listening does not demand of the students intelligent thought; it does not demand careful judgment; the sole requirement of the system is that they shall memorize sufficient facts to pass the examination. The effect of such a system can be shown by asking for a written discussion of a given case. In a recent trial of this sort the attempts of the students to explain the signs and symptoms described brought forth all manner of preposterous statements, illogical reasoning, and baseless conclusions. A systolic murmur was evidence of an uncompensated heart lesion, a liver large with amyloid degeneration was explained as passive congestion, and a tubercular peritonitis was interpreted as cardiac dropsy; and these results appeared at the end of a year of lectures on the subject and after careful clinical instruction in gathering data. The mere accumulation of knowledge does not imply the power of using that knowledge when occasion demands it, any more than the ability to read a foreign language implies the ability to speak it. This neglect to recognize the difference between the active and the passive attitude, and the necessary failure of the lecture system to drill the student to deal thoughtfully with the complicated conditions of real cases, expose the system most freely to objection, and the objection is of fundamental seriousness.

The merits of the lecture system, however, cannot be overlooked. It certainly permits a more systematic treatment of medicine than is possible with clinical cases as a basis. But also it has the greater virtue of giving the instructor opportunity to present his personal experience; to detail the practical points of treatment — the home devices for the care of the sick — not found in books; to illustrate the common failures and mistakes of young physicians; to describe his own ways of meeting emergencies which may make lasting impressions on the students. The skilful lecturer, moreover, can so emphasize the essential points and can illustrate them so effectively that they stand out prominent as the important and memorable facts around which later others may be gathered; and, finally, the spirit of the instructor, his personal influence, can be conveyed to the students more forcibly perhaps in discourse than in any other way. But how rare is such a lecturer! Instead of practical advice the students hear descriptions from the books, instead of illustrated essentials they get abstract details, instead of enthusiasm in the lectures they too often see the indifference born of frequent repetition.

The faults and difficulties of the lecture system have seemed so predominant that in some medical schools instructors have substituted for the lectures in their courses recitations on stated topics. Recitations share nearly all the merits of the lecture system; they allow systematic study, they offer occasion for the personal testimony of the instructor and for the introduction of practical details. But they possess, besides, positive advantages over the lecture system, worthy of note. In the first place, the student must learn from week to week during the year his topics for the recitations. This requirement alone has many important results, chief among which is the continual storing of the student's mind instead of the continual accumulation of his reading matter. This gradual acquisition of knowledge reacts in two ways: first, it makes clinical material more valuable, because the student brings to the clinics a more alert and intelligent attention; and secondly, the repetition of subjects and the association of facts gained thus by repetition tend to make the facts permanent possessions for the student, so that he is less likely to crowd his mind with evanescent information for examinations only. The study for recitations has the further advantage of making the student thoroughly acquainted with his authorities, and the value of these books for later reference is by this very intimacy greatly increased.

The recitations in themselves are also of noteworthy importance. They not only give the student opportunity to correct false impressions, they likewise serve to fix especially in his memory the more essential points of the topic studied. Moreover, the student coming to a recitation is in a proper state of mind to receive new information, or to hear the personal experience of the instructor, or to understand the reasons for emphasis on certain symptoms; for he comes with a mind already prepared with some knowledge of the subject — he has laid by his own efforts a foundation to build upon.

Although the recitation system has striking advantages, it has, as well, important disadvantages which must be considered. Diseases in text-books, like diseases in lectures, are abstractions; they are descriptions of averages or types with no body to give them reality. Now, without a concrete case in view, maintaining a lively attention and keeping the powers of the mind keen and active while reading a book so abstract as most treatises on practice is well-nigh impossible. And to memorize symptoms or points of differential diagnosis directly, without reference to natural relationships, is for most students a very artificial process. Indeed, in lieu of reason as a bond, rhyme or some elusive mnemonic is a common makeshift. Facts learned in this way are not linked in their sequence, they are not associated with the student's previous knowledge; only after much repetition, therefore, do they become a lasting portion of his mental equipment. Moreover, the same serious criticism lodged against didactic lectures for not training the mind to think carefully on medical questions or to deal wisely with the difficulties of a given case may be brought with equal force against the recitation system. It does not demand of the student what practice will demand of him as a physician; it is not, therefore, a satisfactory means of instruction.

The discussion thus far has shown that neither di-

dactic lectures nor recitations are wholly to be condemned or wholly to be commended. Serious faults and decided advantages can be found in either method. These faults surely can be avoided and these advantages retained by the use of proper means. The direct observation and study and treatment of sick people offers undoubtedly the most proper method of learning medicine; it is impossible, however, for students to have a series of real cases following in orderly sequence and existing merely for their instruction. But will not the most immediate substitute for such experience prove a satisfactory manner of teaching the logic of medicine and its necessary facts? Will not the use of a case method of instruction solve the difficulties?

How then can systematic medical training be secured by a study of cases? The answer to this question is at hand. Cases of all the types, variations and complications of almost every disease are to be found in hospital records or in records of the private practice of instructors. These records include a history of family tendencies, notes of previous illness, an account of the onset of the attack, the results of physical examination at the hospital, the story of the ups and downs in the course of the disease, the treatment with its modifications as the symptoms changed, and, in case of death, possibly the findings at autopsy.

Now, the intent of the proposed case system is, in short, to give the students printed data from actual histories. These data are then to be studied and analyzed by the students, who shall be required to consider in every detail the differential diagnosis, the principles of prognosis in the case, and the rational treatment. The students, after having studied the case, shall come to a conference with the instructor, in which all the points in a particular problem shall be discussed. Such in outline is the scheme of study.

A more explicit account of the proposed method will make its workings clearer. And in describing these details the three divisions — presentation, study and discussion of the cases — will be separately treated.

In presenting to the students the printed history and results of examination of a patient, the instructor can take care that only so much is stated as will stimulate the students to more careful thought and discrimination in their study. The treatment of the patient may be withheld and the students be made to prescribe treatment according to their diagnosis. If the illness ended fatally and autopsy was performed, the findings of the pathologist should be retained to correct inferences drawn from clinical data. In the study of a particular disease cases showing typical variations (as, for example, the different forms of typhoid fever), or cases illustrating the disease in various stages, or cases in which the real nature of the illness is obscured by complications, may be given out at the same time for purposes of comparison; or other diseases with similar symptoms (as meningitis and miliary tuberculosis in the study of typhoid fever) may be introduced to make a more searching demand on the discriminating powers of the student. Likewise cases showing signal instances of common errors and oversights, or bringing out little matters of practical treatment and domestic expedients, would be of great value. The presenting of cases is thus capable of the most elastic adaptation to the needs of the students, according to the judgment of the instructor.

With records of patients in their hands the students now begin their active investigation. It is supposed that their only preparation is a previous study of the scientific groundwork — anatomy, physiology, pathology and therapeutics — and that they have heard no lectures on the practice of medicine. That the students will have difficulties at the start, even with simple cases, is certain, but that work done for themselves is far superior, as training, to the acceptance of stated results from another is also certain. That mistakes in judgment and reasoning will surely be made is not regretted, for mistakes are often the most impressive teachers. First the student reads the history, then analyzes the relations of the symptoms, selects what seem to him the primary disturbances, and sets to work to make his diagnosis. He goes to the textbook for reference; he must study all the diseases which his case might represent in order to establish his opinion. If cases of different diseases, with similar symptoms, have been given him, he must compare them and discriminate between them, or learn the further examination necessary to settle the decision. He must be ready not only to detail the therapeutic indications in the case as it stands, but also to treat such complications of the course of illness as the instructor may suggest. The opportunity for individual study and support of special treatment, such as hydrotherapy, in relation to the patient under consideration, here presents itself. Meanwhile the student is incidentally picking up the etiology and special pathology of the affection. All this work which he does for himself on the data of an actual hospital case, his diagnosis, his opinions, his treatment, are subject to review in the classroom and will be criticised not only by his fellow students, who have studied the same case, but also by the instructor. This fact alone, wholly apart from the future value to him as a practitioner, is a strong incentive to careful preparation and sound thinking in advance of the conference.

The conference consists of a discussion of all the aspects of a given case or set of cases, under the direction of an instructor, who makes suggestions or expresses his own opinions as they seem necessary. The conference is a real conference, because all participants come to it with considerable knowledge of the subject already secured. The instructor first calls upon one of the students to state the case, on another to analyze the symptoms and venture a diagnosis, on another to present the differential points, on still another to suggest treatment. Meanwhile other students are asked for their opinions of statements made, or may voluntarily offer their criticisms. The various sources which the students have consulted are naturally brought together in the discussion, and a most valuable opportunity is thereby offered for comparing criteria of diagnosis and modes of treatment of different authorities. A second case brings material for noting similarities and differences, and with each additional instance the possibilities of comparison and generalization increase. Throughout the conference the instructor acts as moderator, guiding the discussion along profitable lines, correcting false statements, exposing the weakness of unsupported opinions, or suggesting hypothetical changes or modifying conditions in the case, which will compel the students to think quickly and accurately. The instructor must also be ready to answer from his own large experience many questions; this phase of the system is particularly valuable not only in keeping the instructor alert and keen,

but also in giving him an insight into student difficulties and shortcomings. Thus the student advances with his study; he learns to express himself clearly, he learns to judge precisely and definitely the data of medical cases, and in standing by his judgment in the conference he is strengthening the inestimable habit of intellectual self-reliance. And while his ability to reason closely and judge thoughtfully is thus being developed, and while he is gaining skill in analysis and synthesis, he is also gaining the other object of medical study, a practical working knowledge of the facts of medicine.

A comparison of the general characteristics of the case system already mentioned, with the merits and defects of the common methods of teaching, will bring out more distinctly certain special characteristics of the proposed scheme. The case system, in the first place, avoids the objectionable features of didactic lectures. The student does not spend his time duplicating his reading matter by lecture notes to be set aside for later study; he is learning his facts gradually throughout the year by actually applying them in his work. Instead of depending on his uncertain records of lectures, he is training himself by practical experience to use his books just as later he may have to use them in reference to his own patients. Not only does the system avoid these objections to didactic lectures, it has as well the positive advantages of both the lectures and the recitations. It shares with them the virtue of presenting the subject of medicine in an orderly and systematic manner, inasmuch as the cases are arranged to develop step by step the particular disease in all its various phases and relationship. It also, like the other methods, offers abundant opportunity for the instructor to emphasize essentials and to give his own observations, but with greatly increased value to the students, because the instructor's words go to minds already prepared by knowledge of illustrative cases. Finally, the spirit of the instructor, the element of personal contact, in shaping student ideals is surely revealed as a much stronger and more real factor in the free intercourse of the conference than in a formal lecture or recitation.

Every one of the merits claimed as peculiar to the recitation system, the case method will duplicate. In it, just as by reciting, the student is continually learning instead of taking notes and getting ready to learn. He has the same chance in the conference to correct false impressions that he has in the recitation. In supplying knowledge which will increase the value of clinics the study of cases is even superior to the study of text-books alone, since concrete instances make more definite and permanent impressions than disembodied descriptions. The student, with actual cases and their symptom groups in mind, is quick to detect the absence of a usual sign, or the presence of a rare condition, and these now become a part of his already acquired experience. And as for the pernicious method of learning medicine by cramming for examinations, the very nature of the study of cases forbids it.

The case system not only avoids the defects and includes the merits of didactic lecture and the recitation, the system also has qualities and possibilities which surpass in value the best features of either of the common methods.

The first of the distinct and peculiar characteristics of the study of cases is its power to rouse enthusiasm. Nothing is more significant than the attitude of students towards a medical problem on which a number are working together. For example, the following single case was by chance given to a class of students for discussion: A boy of seven years had no noteworthy illness until, at five years of age, he had scarlet fever, with acute nephritis in complication. He was seen six months before the present illness, when he had grippe, with acute middle ear. The urine at this time showed no evidence of nephritis. His general condition has been fairly good since.

The present illness began with vomiting and high temperature, 104°. He was seen by a consultant two days later. During these two days he had grown worse. The temperature had remained above 104°. The vomiting had continued at intervals, but was not so severe or frequent as at first. He had become apathetic, but complained of pain when handled. The bowels were constipated. The tongue was coated.

At the examination on the third day of the illness he was found fairly developed and nourished. Though somnolent, he could be roused and he cried out when handled. There was no retraction or rigidity of the head. The pupils were equal and reacted normally. The face was flushed. The breathing was rapid and superficial. The pulse was strong and rapid. Nothing was detected in the lungs except diminished vesicular respiration in both backs below the scapulæ. The cardiac impulse was felt in the fourth space just inside the *right* mammary line. It was somewhat increased in strength, the heart sounds were distinct, there was no murmur, the second sound was not accentuated, there was no impulse felt to the left of the sternum or in the epigastrium. The abdominal muscles were so tense that palpation was impossible, not from any localized tenderness but apparently from tenderness all over the abdomen. Rectal examination was negative. Urine was negative.

Opiates were required to relieve pain. There had been no vomiting for twelve hours. A large movement of the bowels followed the administration of calomel on the previous day.

Such interest as resulted, such debating among themselves as this problem of diagnosis alone aroused among the students would be absolutely impossible with the usual methods of teaching. Impressions made under such conditions, when the attention is naturally eager and keen, are deep and lasting. It is the particular patient, the concrete instance, that gives body and form to text-book abstractions, holds the attention, and stimulates the reasoning power. Neither the lecture nor the recitation stirs enthusiasm; the case system, however, is on record as having accomplished this result most successfully.[1]

The correlation of the scientific and clinical aspects of medicine is a second important possibility which the study of cases may claim. At the present time in most schools two years are spent on anatomy, physiology, pathology and therapeutics with their various branches. Rarely, however, is any connection between these subjects and their clinical bearings made clear. The subjects are studied and then pigeon-holed as finished work, while the student proceeds to learn symptoms and treatment anew, not in any relation to what he has already learned, but as something apart and unrelated. With a good leader, however, and the habit of careful thought established among the students, the underlying pathological condition, the disturbed physiology,

[1] Vide infra.

the therapeutic action of the drugs employed, could constantly be brought forth to give the cases a rational explanation and to teach the students the deeper insight which vision through general principles affords.

By far the most important aspect of the case system, however, is its great value in drilling the mind of the student to meet intelligently the difficulties of practice. With present methods of instruction, skill in logical thinking, which makes a knowledge a power, is not infrequently sacrificed or impaired by the strained effort at accumulating the very knowledge to be used. How many students will exercise independent judgment or do critical reading while preparing for a recitation a dozen pages of any standard work on practice? To be sure, such preparation in some instances develops an extraordinary ability to memorize; but the mind is thereby only burdened with an unwieldy multitude of facts, while there is not the slightest necessity for any effort at real intellectual construction. Instead let the students have a number of cases with similar symptoms, but with peculiarities and complications, and can any student fail to puzzle over them and study them? And having studied them will not the conference at which his diagnosis and treatment are either confirmed or questioned mean more to him and produce a more lasting impression than any lecture? To deal with cases, to draw correct inductions, as an interpreter, from his data, as an observer; to apply proper treatment — these make the work of a doctor. The clinics train the medical student in observation; nothing at present requires him to look carefully on all sides of many cases, to think clearly and accurately, or to have reasons for his conclusions. Are not these powers among the most indispensable qualities of a physician? If so, the method bringing these faculties into constant use and discipline, and at the same time demanding the most thorough and precise knowledge, is certainly best adapted for the study of medicine.

Criticisms undoubtedly can be brought against the method of teaching above described. Some may assert that devotion to a printed record is, in itself, an unpractical way to learn to practise medicine. Although it is conceded that such preparation is not so effectual as real care of the sick, yet the objection may be met in part by the greater system and completeness assured by the case method of instruction than is probable in an experience with a shifting throng in the hospital wards; but more particularly is the objection answered by the fact that, with the hospital experience necessarily excluded from the undergraduate years, the study of actual cases is certainly more practical than the present lecture system or the recitations. Indeed, under prevailing methods, it is a wonder that the dangerous tendency of inexperienced minds to vague and fantastic theorizing is not more prevalent. To such a tendency an effective check is certainly present in the discussion of the cases, for one student's weakness meets another student's strength and the instructor is a practical man. Moreover the case method is not meant to replace clinical instruction. At the clinics the students are drilled by their corrected efforts to secure, by thorough and discriminating observation, reliable clinical data; with the cases they are drilled by their corrected efforts to judge with care exactly this same sort of data. The two methods thus go hand in hand with mutual benefit: the clinics keeping the student in touch with human life and training him to note its variations; the cases pointing out what to watch for, showing the importance of complete examination, and teaching how to interpret observations as they are made.

A second objection that may be urged is, that the case system requires more time than the strictly text-book systems. So far as the consideration of a certain number of topics is concerned, this objection is admitted to be valid, but that the proposed system requires a longer time to discipline the mind for the successful practice of medicine is flatly denied. First, the particular points learned while studying one narrow subject are a small part of the total acquisition. Many diseases not directly connected with the disease under consideration may be involved or suggested, and these the student can exclude, or accept as possible conditions, only after careful research. The points thus incidentally learned are fixed in the mind as they never could be by disconnected reading or by lectures, for instead of being presented as independent facts they occur as an integral part of a living problem. More important, however, than this casual acquisition of knowledge is the fundamental training which the method assures the student exactly along the lines which his future labors as a physician will follow. To meet the criticism of his classmates in the conference he must be careful to analyze his data, discriminate shrewdly, and judge fairly; he is led to use every means to fortify himself either for his own instruction or to answer his critic, be it professor or fellow-student. Thus before graduation he is acquiring that ready store of information, that facility for quick and accurate thought, that abundance of resource, which mark the best physicians; while the student of the text-book methods only begins to realize the value of these talents after he has ceased to be a student and has become a practitioner.

The question of the practicability of the whole scheme here outlined has probably arisen many times long ere now. Is not the plan all theoretical? Is there any instance of the use of the system to justify the claims made for it? The fact of presenting cases in medicine for purposes of conference cannot be gainsaid. Every district medical society uses records in precisely the manner of the proposed system whenever a member reads a paper describing an experience in his own practice. The only difference here lies in the nature of the discussion which follows; the students must speak from a common study of the same hospital reports, the doctors have their own past experience to draw upon. Moreover, the value of a discussion of cases in showing the practical powers of the physician is also recognized. In certain courses full accounts of patients are set on examination papers, with a requirement that the candidate shall analyze the symptoms, make a differential diagnosis and give the prognosis and treatment. Now if such a method is employed to test a man's ability to think clearly and apply his knowledge accurately in medical practice, is there any reason why it is not just as applicable in training him for exactly the same work? Indeed the case system, as here described, is already used in part in medical education. The few instances of this partial use of the plan, while only indicating its possible importance, are particularly significant. The obstetrical conferences in the course in obstetrics in the Harvard Medical School offer a striking example of the conference phase of the case system. At these conferences students read their hospital records of their own experience in obstetrical cases. These records are selected by the instructor so as to develop

the subject and to bring out its complications and difficulties in a perfectly orderly and systematic fashion. Each report of a case includes a full description of the conditions present and a detailed account of the handling of the situation. If the listening students in the conference knew but little of the subject, the reading of a report would not be unlike the reading of a lecture. But the listening students themselves have had similar experiences, and, instead of sitting with minds dulled in receptivity, they are alert and actively following the account in order to question the reader on his methods, his opinions, his results. And when the students fail to bring out all of the important points in the case, the instructor, a practical man, indicates the significance of the unnoted features. Such is the recognized value of this discussion of the actual conditions of practice that any question of the possibility of successfully applying the case method in medical instruction is here completely answered.

Undoubtedly the most brilliant example thus far of the use of cases in education is seen in the study of law.[1] The change from the text-book to the case system wrought out in the Harvard Law School has been called America's greatest contribution to educational reform. The newer method has roused an ardor and a keenness of interest among the students such as was never known before. They learn their law not by dreary grubbing at text-books or lecture notes, but by vigorously "threshing out a case" with one another. And for its methods and for its results the Harvard Law School is regarded by competent observers[2] as perhaps the foremost centre of legal education in the English-speaking world.

The case method is simply another application of the inductive method to teaching. The inductive method holds its strong position in education to-day because it requires of the student accurate judgment, close reasoning, precise expression and wise employment of his knowledge. It is a method which demands for a long period a student's best endeavors in the full use of all his faculties, but it rewards him with a strength and self-reliance unattainable in any other way. He learns, on the one hand, to avoid smartness and claptrap diagnosis, and on the other, the routine thoughtlessness of the "practical" physician. The method is practical; it will turn out practical men in the best meaning of that term.

Clinical Department.

A CASE OF RELAPSING FEVER.

BY GEORGE O. WARD, M.D.,
Visiting Physician to the City Hospital and Memorial Hospital, Worcester, Mass.

RELAPSING fever has not been epidemic in this country since 1869, when it appeared in force in Philadelphia. The statistics and data of this epidemic, as investigated and reported by Parry, appear in standard medical literature. Sporadic cases are so rare as to be of exceeding interest. For this reason the author has chosen to report this case to the JOURNAL. I wish to say at the outset that this uncommon diagnosis was not made because of any partiality therefor on the part of myself or my house officer, for we were forced to our conclusion in differential diagnosis by rigid exclusion of other possible causes for the initial rise of temperature, and only convinced by the punctual appearance of the relapse.

The patient, a young Armenian immigrant, eighteen years old, had just arrived, on August 9, 1899, with his mother, direct from Turkey-in-Asia, via England. They had been five weeks on the journey, thirteen days of which were taken in the passage from some English port to New York. Neither he nor his mother could speak a word of English. Hence all data had to be obtained through the interpreter. Both were very sick on board ship, whether from *mal-de-mer* or an initial paroxysm of this fever I have not been able to decide. But both mother and son were taken sick on the same day after arrival in Worcester, with like symptoms. The former remained with friends for four days, when she entered the Memorial Hospital; the latter entered the City Hospital at once.

The crisis of the mother's fever occurred simultaneously with that of her son. She did not have relapse; but, in view of the evident intimate connection of the two cases, I think it fairly probable that the illness of both previous to landing may have been the initial run of the fever.

August 10th. The son, on his entrance into the City Hospital, showed physiognomy characteristic of his race. His previous medical history was negative. His habits were good, and he denied venereal disease. Yesterday he had very severe headache and slight diarrhea. Later he had severe chill, high fever, with much muscular pain. Later still, in the evening, he had profuse epistaxis, to control which both nostrils had to be plugged. At his entrance, his temperature was 104°, his pulse 100, his respiration 22. His expression was dull and apathetic. His skin was moist and very dark, suggesting jaundice. No eruption of any kind was to be seen on his body. His pupils were normal. His nostrils were plugged, and epistaxis followed any attempt to remove plugs. His tongue was dry, with brown coat. Sordes were on teeth, lips and gums. Heart and lungs were negative. There was no tenderness of abdomen, but both liver and spleen were easily palpable. Reflexes were sluggish. There was no edema. The urine was negative, the diazo reaction being absent. The patient was put on diet of liquids and ordered to have baths when temperature is above 102.5°. Ice cap was applied to head. Strychnia, one-sixtieth grain every four hours. The temperature was ordered to be taken and charted every four hours, as is our routine.

August 11th. The Widal reaction is negative, and the diazo also. Plasmodium malariæ was looked for but was not found. Leucocytosis, 6,200. Plugs were removed from nostrils. No epistaxis followed. Temperature was still high, and patient was very apathetic but not delirious.

August 12th. Temperature was still above 105°, and baths had little effect; pulse was not of good character. Spiritus frumenti, two drachms ordered every four hours. Slight epistaxis. Patient looked bad.

August 13th. Between eleven last night and three this morning, patient's temperature fell from 104.8° to 97.2° (nearly 8° in less than four hours), and his

[1] See Keener: American Law Review, xxviii, for an excellent account of the workings of the method in law. The writer is indebted to this article for suggestions.
[2] Nation, June 8, 1899.

pulse simultaneously fell from 110 to 68. There were no signs of collapse, and pulse was of good character. Sweating was *very* profuse. Examination of chest was negative, as also was a second serum examination. Leucocytosis, 500. Patient brightened up during the

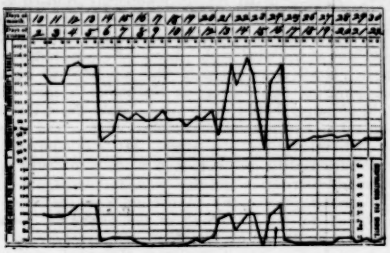

Chart of this case.

day and at night was feeling fairly comfortable. Constipation.

August 16th. Temperature soon rose to between 99° and 100° and has continued so. Pulse has continued at about 70. Stimulants were omitted. Patient seems comfortable and takes interest in surroundings. Shows signs of hunger. Denies subjective symptoms.

August 21st. Patient has been feeling pretty comfortable since date of last note. Has been on diet of semi-solids, and has been allowed to sit up a little in bed. His skin appears to have cleared as though he had been previously jaundiced. This afternoon his temperature shot up again from 97.8° to 105.5° (rising nearly 8° in less thane ight hours), but without marked subjective symptoms. Leucocytosis, 12,000.

August 23d. Temperature has remained persistently high since last note, until 11 A. M. to-day, when it fell by crisis from 105.5° to 96° (falling 9.5° in less than eight hours). He perspired very profusely and showed more evidence of collapse than in previous crises, so that some stimulant was given. He complained of no symptoms, but during all this relapse he has been very apathetic. The blood has, during this relapse, been examined daily for the spirillum Obermeier and plasmodium malariæ but without success.

August 24th. Between three and eleven this forenoon temperature rose again from 97° to 105.6°, and,

Chart of Murchison.

after continuing high for four hours, fell again to 95.6° (a drop of 9° in less than eight hours). This crisis, like the others, was accompanied by profuse sweating. Patient is very apathetic, with fair pulse at 60.

August 25th. During last night the patient's temperature fell to 95.2°, but this forenoon it is 97°. The patient looks brighter and has no symptoms.

September 1st. For the six days after the last note, patient carried subnormal temperature, averaging about 97°, as recorded on four-hour charts. Yesterday and to-day the temperature has ranged in vicinity of 101°, without symptoms. Patient has improved much in general condition. Complains much of hunger, and is to-day allowed to get up and eat house diet. Leucocyte count normal.

September 9th. Convalescence was steady from last date and patient was this day discharged well.

The above notes present a clinical picture fairly typical of relapsing fever. The temperature chart, as depicted in the authorities, is so striking and so utterly unlike that of any other disease, that I wish to exhibit one from Murchison in comparison with that of the case above described. The "abrupt crisis, characterized by prodigious and sudden fall of temperature unequalled in any other condition of disease" (Murchison), is still more graphically shown by our four-hour chart, from which record I have verbally quoted in the notes. But if the chart of the case just reviewed be properly superimposed on the chart of Murchison they will be found to agree so strikingly that one can hardly suggest that they can arise from cases dissimilar in nature.

The failure to detect the spirillum of Obermeier is not remarkable, as it was not looked for until the relapse, and it may not have been present. If the spirillum had been found, I think it would have been only regarded as evidence comfirmatory of a diagnosis otherwise well established by clinical phenomena and a typical temperature record.

I wish to hereby acknowledge my indebtedness to my house physician, Dr. George A. Dix, for his faithful study of this case and for his careful clinical notes taken thereon.

ON THE TREATMENT OF PAIN IN TABES DORSALIS; REPORT OF A CASE.

BY ALFRED H. LINDSTRÖM, M.D., BOSTON.

The temporary amelioration and suppression of pain occurring during the crises of tabes dorsalis by the use of appropriate chemicals and drugs is, no doubt, readily accomplished. But the repeated and frequent use of analgesic chemicals, especially coal-tar derivatives, is unquestionably deleterious to the general health of the patient, and since the successful management of a tabetic patient demands the most careful attention to his general health and his constitutional resistive powers, it is obvious that such medication should be avoided as much as possible. Methods of diminishing and alleviating the intensely distressing pains of tabes, not involving injury to the general health, would therefore seem to merit attention. A number of mechanical procedures have been suggested, and used with more or less success, such as surgical and postural stretching of the sciatic nerves, suspension, various forms of counterirritation, including the use of static sparks, other forms of electricity, direct pressure on the sciatic nerve, the use of friction with ice, ice in other forms, hot baths, cold douches and sprays to the spine, etc. Because of the marked success resulting from postural or mechanical stretching in the following case, its publication would seem justifiable.

The patient, a business man, is forty years old. About ten years ago he began to have pains in the legs, chiefly below the knee, occurring in irregularly recurring periods of increasing severity. They were thought to be of rheumatic origin, since damp weather seemed to cause them. Antirheumatic treatment was, however, of no avail, and the attacks grew more painful, and although a considerable interval of comparative comfort would supervene occasionally after a bad attack, the frequency of recurrence seemed to increase. This state of affairs lasted about nine years, during which time the cause of the pains remained a puzzle to the patient and his numerous medical advisers. The patient exhibited a remarkable degree of endurance throughout this period, generally refusing the use of any remedies suggested for the relief of his acute suffering, fearing that he might contract some drug habit, or that his general health would be affected by their use. As the intensity of his suffering increased, however, and reached beyond his limit of endurance, he finally resorted to the free use of whiskey, drinking large quantities during the attacks. No other symptoms appeared until about a year ago, when after three weeks of unusually severe mental and physical exertion, due to business enterprise, he noticed unsteadiness of walking in the dark. This he accounted for by the very free indulgence in whiskey, induced by the unprecedented intensity of the pain about this time. Other symptoms now developed in rapid succession; a distinct girdle sensation, or feeling of constriction about the waist, puzzled him greatly, and slight urinary defects were noticed. His gait was impaired, and walking without help became difficult.

After this rather rapid advance of the disease the patient had to abandon his business and, determined on a stubborn fight against his physical decay, he gave his entire attention to the care of his health.

About six months later the patient came under my observation. Physical examination showed absence of both knee-jerks, even on re-enforcement, lack of pupillary reaction to light, and marked typical ataxia of the legs. Sensation was affected in toes and feet but otherwise normal. The patient could not maintain his equilibrium with closed eyes, even when standing with feet apart. There was no impairment of vision, no trophic changes, and the muscular strength of the legs remained normal. Sexual function not affected. The patient was nervous and easily startled; but barring the presence of traces of acute suffering in his face, he presented a clearly cut and well-proportioned physical makeup. He never had chancre or gonorrhea; married ten years ago, and has a healthy boy eight years of age. The initial pain began before marriage. Had a fall from a height of about four feet, striking on his back, about thirteen years ago; suffered from pain in the back some time afterwards, but recovered entirely from immediate effects of this fall in a comparatively short time.

The most urgent need of the patient at this time was immediate relief from his suffering. The pains were so severe as to entirely prevent sleep; for more than ten days sleep had been badly interrupted, and during the last two nights the patient was utterly unable to secure a moment's rest. His wife feared that he would commit suicide, or become insane, his actions were so strange. He would scramble from one room to another, busying himself with anything he could think of, often something absurd or trivial, trying to forget his pain; he would clutch his legs, shake his fists, and go through weird physical contortions; shortly speaking, he was actually frantic with pain, and tried to escape his torments, but could not; he described the pains as instantaneous streaks of intense heat tearing through his legs, making him wince and cry. In spite of all this, he stubbornly refused to accept any opiate, or any other analgesic remedy; he had now been cautioned against the use of alcohol, also, and was at his wits' end. Lack of sleep and the repeated shock from the pain had produced an imprint of suffering and distress on the patient's face which told his story better than words could do. The case offered an exceptional opportunity to test the efficacy of some mechanical procedure. (It is my impression that various attempts had been made to procure relief by counterirritation and the use of liniments, but without success, prior to my connection with the case.) I resolved to try stretching of the sciatic by posture, namely, by flexion of the thigh and extension of the leg and foot.

On the 17th of October, 1898, I applied the first extension or stretching; I kept each sciatic nerve in a state of tension during two minutes. At the expiration of this time the patient complained of numbness of the feet and slight distress, due to tension, in the popliteal space. The patient remained in bed quietly about half an hour after the operation, chatting pleasantly, and entirely free from pain, but the numbness of the feet persisted. On attempting to walk it was noticed that the ataxia of the legs had increased considerably, so much so that the patient feared to attempt it alone. This was probably due to the anesthesia (numbness) of the feet, since the gait improved with the disappearance of this symptom the following day. During the night the patient had several hours of sound sleep, but woke up early in the morning with acute pain, although not as severe as the previous night. In the afternoon another stretching was performed, the procedure lasting about three minutes to each leg. The immediate results were the same as on the previous day, with, possibly, a trifle more pronounced numbness and uncertainty of movement of the legs when attempting to walk. The absence of pain was more complete, and seemed almost phenomenal. The patient slept well throughout the night, and received me in a state of high glee when I made my visit on the afternoon of the following day. A third application of the method was made, two minutes to each leg being thought sufficient. It was agreed that if severe pains should recur, I was to be informed, and another operation performed the following day, otherwise it was thought best to defer further treatment until at least two days had elapsed. The condition of the patient remained satisfactory, however, and the next stretching was done on the afternoon of the second day after the previous visit; the fifth and last operation was performed after the lapse of another forty-eight hours, during which time the patient had been practically free from pain.

The subsequent history of this patient has been very satisfactory. He has had a few light attacks of pain during this summer, usually caused by too much walking, climbing of hills, getting upstairs too many times a day, or, generally speaking, by injudicious physical exertion.

The general treatment of this case consisted of large, increasing doses of iodide of potash, administered

periodically, free use of artificial Marienbad water, cod-liver oil, systematic co-ordination exercises, open-air life as much as possible, and careful hygiene, including daily sponging with diluted alcohol, followed by brisk friction and slapping of the skin. He was also directed to abstain from coffee, tea, alcohol, tobacco and sexual intercourse, until material improvement had occurred. He was a very conscientious patient and lived up to the rules faithfully. The iodide was not given as a specific remedy, since there was absolutely no evidence of specific disease, either in the history or in the physical examination. It was given empirically for whatever effect it might have toward combating the progress of the malady through its eliminative action, and for its action upon the glandular system; the indication for its use was based upon the assumption that in this case the pathological changes of structure evidently going on were possibly due to the effects of autotoxicity, dependent upon disturbed nutritive functions. The Marienbad water was given for the same reason, namely, its eliminative and corrective effect. There was absolutely no tuberculous tendency in this case, but the cod-liver oil was suggested largely as an article of diet, to bring nutrition to as high a degree as possible; the oil was taken without objection and there was no digestive obstacle.

The exercises were so devised as to involve movements related to and associated with walking and balancing, and were practised on a slowly progressive scale. I mean by that, that one set of exercises was adhered to until they were done with nearly perfect co-ordination.

The patient was last seen by me on the 30th of September, and he presented a very satisfactory appearance. He had gained seven pounds in weight; his walking was fairly good, and the pains were of only trifling degree. He could turn about quickly without fear of falling, and walked across a busy street in my company without any assistance, except a cane, which was useful to him, no doubt, but not absolutely necessary.

The almost phenomenal cessation of pain immediately after the stretching may, of course, possibly be explained by assuming the two events as a mere coincidence. If so, it was a very happy one for the patient. To attempt a satisfactory, rational explanation is perhaps a difficult or impossible task. Whether due to physical changes in the peripheral part of the nerve fibres, such as elongation, for instance, diminishing their conductivity, or local compression in the region of the pelvic exit, or to both, or to other changes; or whether due to changes in the more centripetal part of the nerve, or in the cord itself, such as alteration of the ordinary anatomical relationship of nerve fibres and nerve cells, or of nerve cells and their processes, impairing their power of conductivity and transference of nerve impulse, is obviously impossible to decide. But if it is accepted that the pains are due to the presence of irritating toxins, producing an inflammatory or degenerative process in the nerve elements, then it would seem plausible to ascribe the cessation of pain to lessened conductivity of the sensory neuron, resulting from probable alteration, presumably temporary, in its structure, since it is evident that putting the nerve in a state of tension could not in any way influence the primary cause of the pains, but would affect the structure of the tissues in a mechanical way.

A fact worth noting in connection with tabes, and to which Dr. James J. Putnam has called attention, is the extreme flexibility of the hip-joint at an early stage of the disease. In this case, although in a comparatively early stage of development (conclusive tabetic symptoms having been present only a few months), the degree of flexion obtained was amazing, and greatly surprised the patient. Having flexed the thigh close to the abdomen, I succeeded in bringing the patient's leg and foot on a level with his face, which position was maintained during two and three minutes, respectively, as stated above. In doing this, great care was taken not to use undue force, or any sudden pressure. I mention this because in text-books, where this treatment has been spoken of, the stretching has been described as being accomplished by a *sudden* extension of the leg upon the thigh, after flexion of the latter. Such a sudden maneuvre would be dangerous in a tabetic patient, whose bones are apt to be fragile and liable to fracture. Also, the danger of subluxation at the hip-joint during such extreme flexion should be borne in mind and guarded against. I have recorded this case at some length, because of the successful results obtained, because of the complete absence of any medication for pain, and, also, because of the opportunity for continued observation for a considerable period after treatment afforded by it.

Perhaps it is unnecessary to state that it is not my intention to challenge the usefulness of the many very effective analgesic remedies *in toto*; I merely wish to present the facts in this case for what they may be worth in connection with the treatment of pain due to tabes and kindred affections.

A PISTOL WOUND OF THE ABDOMEN.

BY C. A. ATWOOD, M.D., TAUNTON, MASS.

J. McM., age twenty-eight years, single, occupation, painter, was suddenly awakened from sleep at 1.45 A. M., Tuesday, November 21, 1899, by the presence of his brother-in-law, who had obtained entrance to the house by means of ladder and window. The brother-in-law immediately discharged a revolver, the shot taking effect in McM's abdomen. He was removed to Morton Hospital between 3 and 4 A. M.

Physical examination.—Pulse very weak, 150; skin ashy; cold perspiration. Left side of abdomen in mammary line below costal cartilages showed a powder burned area about two inches in diameter surrounding an opening, size of pistol ball. Diagnosis: Pistol wound in abdomen. I saw the patient about 4 A. M., and advised an immediate laparotomy. The patient was etherized and an incision made in the median line between ensiform cartilage and umbilicus. The stomach was pulled into the wound, near greater curvature at pyloric end on the anterior surface; a perforation was found and closed by suture. Incision carried half-way between umbilicus and pubes. The small intestines were found perforated seven times, and the holes closed by Czerny-Lembert sutures. The intestines were thoroughly looked over on a hot sterile towel and no more perforations found. An opening was then made in the peritoneum between the transverse colon and greater curvature of the stomach; a perforation on posterior wall of stomach found and sutured. There was some hemorrhage and moderate amount of blood in abdominal cavity from injured mesenteric vessels; these were secured. The abdominal cavity was flushed

with boiled water and filled with salt solution. The wound closed tight; antiseptic gauze dressing applied.

Patient died at 10 P. M., after all means to rally him from the shock had been tried and failed.

Autopsy by medical examiner. — Death from shock. All perforations closed. The pistol ball had perforated the iliacus muscle and was found resting against the ilium.

Reports of Societies.

SURGICAL SECTION OF THE SUFFOLK DISTRICT MEDICAL SOCIETY.

F. G. BALCH, M.D., SECRETARY.

REGULAR meeting, Wednesday, November 1, 1899, DR. J. W. ELLIOT in the chair.

DR. J. C. WARREN demonstrated on the cadaver

ALLIS'S METHOD OF REDUCING A DISLOCATION OF THE HIP.

He explained also Allis's theory of the production of dislocations of the hip-joint. According to this author, the head of the femur is forced out of the acetabulum on to the dorsum by flexion, adduction, and rotation inwards and not by thrust, as was assumed by Bigelow. Forcible extreme abduction produces dislocation forwards.

Allis's rule for reducing dislocations on to dorsum, or, as he calls them, "outward dislocations," is: "Flex; turn leg out; lift; turn leg in; extend." Dr. Warren stated that he had tried this method on one occasion with satisfactory results. The rule for reduction of the thyroid dislocation, or dislocation forwards, is to flex and abduct the femur in order to bring the head into the position it occupied when it first left the socket. Traction outwards in the long axis of the femur brings the head over the socket, when it is pushed in by the thumbs of an assistant.

Dr. Warren also showed

A DISSECTION OF THE SHOULDER, EXPLAINING THE ACTION OF KOCHER'S METHOD.

On turning up the deltoid and separating the pectoralis major from its humeral attachment the head of the bone is seen lying under the coracobrachialis and biceps tendons. The supraspinatus and infraspinatus and teres minor are stretched across the glenoid cavity. As the humerus is strongly everted the head begins to roll out from the coracoid tendons and the spinatus group of muscles is relaxed. As the elbow is carried towards the median line the head of the humerus became more prominent and pushes the folds of the capsule before it. When finally the arm is inverted, the head of the bone takes in the slack of the capsule and rolls beneath it into the socket.

DR. CHEEVER: My experience with the thigh has not been very great, but those cases that I have had I have reduced by the Bigelow method, and never had the experience of having the capsule or anything intervene which prevented perfect reduction, in the recent case. Not so, however, with the shoulder, because all the dislocations of the shoulder that I have reduced have been done before the introduction of Kocher's method by one of two ways, as follows: The patient was etherized, laid on the floor or bed, the arm was pulled downwards, and with aid of the foot in the axilla the bone was pried into place. The other method was to lay the patient on the floor and put the foot on the patient's shoulder, holding the scapula down, and draw the arm directly up, and the head was lifted up into the socket. By those methods it has several times happened to me to have afterwards what Dr. Warren has termed subluxation, that is to say, a perfect reduction at the moment, but not staying, and we used to ascribe it to a fracture of the glenoid cavity or to some laceration of the ligaments. I can conceive it was probably due to the rude method of reduction which failed to unfold and eliminate all the fibres of the capsule which lay between the head of the bone and the socket. I do remember reduction by pulleys when ether was first coming in. I saw one of those cases done at the Massachusetts General Hospital in which the femur was drawn into place without ether, and I remember very well how anxious the surgeons and attendants were that the force should be applied very gradually, and that no sudden jar should take place in the performance for fear of breaking the neck of the bone, which occasionally did occur in spite of the best efforts. Subsequently I assisted Dr. Bigelow in some of his dissections, and remember very well what a great step in advance it was when he explained the anatomy of the hip dislocations; and all such dislocations that I have had to reduce I have been able to reduce by his method except one sent to us at the City Hospital a good many years ago, where a strong young sailor had been taken care of by natural bone setters, and the dislocation of the femur, if it had ever been recognized, had never been reduced. He was brought to the hospital after some weeks, and repeated efforts made at reduction with ether with manipulation, and by the aid of a triangle rigged with pulleys, etc., but they all failed.

I have nothing more to add except one case that perhaps may be a little in controversion of what Dr. Allis says of the femur not being put out of place by a thrust. It has been my rather rare fortune to have one case of compound dislocation of the femur with the bone unbroken. Those cases are very rare, and I think something less than fifteen or twenty are on record as having been observed. In this case the femur was driven out of the socket up on to the pubes and emerged between the muscles and skin in front of the thigh, and the head of the femur looked directly upwards and was unbroken — a compound dislocation of the femur. It took place in this way. The man was one of those persons employed in unloading heavy boxes of goods in the wholesale district. He was trying to pull a loaded box off the wagon by the aid of cotton hooks and braced himself back, and the box came down and struck against his knee, while the steps of the store were against the back of the pelvis, and the bone was driven directly out, without the possibility of rotation. Of course that would be an extremely rare accident, but illustrates the fact that if the force is applied in the right way the femur can not only be driven out of the socket, but through the soft parts.

I had a woman brought in once who had the femur dislocated by a falling sign, and it struck directly on the back of the trochanter in the way that used to be thought the usual way of producing dislocation, and the bone was knocked out of place and down into the thyroid foramen. That was reduced. In that case she may have bent her body and had the motion of

rotation and abduction which assisted in throwing it out; but in the compound dislocation it seems as if it must have been the impinging of direct force; and confirmation of that is that, the patient dying at the end of two or three days, further injuries were found, inasmuch as there were partial fracture of the lumbar vertebræ and laceration of the aorta just where it goes over the edge of the pelvis and is ready to bifurcate into the iliacs.

I have read Dr. Allis's book, which he was kind enough to send me, and it is extremely ingenious. I have been confused by the multitude of its diagrams. I have found it impossible, not having practical cases to use it on frequently, to carry his method firmly in my mind. I think that this demonstration would enable me to do it better. I think the part assigned to the sciatic nerve is very interesting, but of course I should like to see it verified by an absolute case, and I do not understand that Dr. Allis has had an absolute case that proves that it has occurred.

Dr. Lund: I would like to say with reference to Allis's theories of production of these dislocations by twist rather than by thrust, that in the experiments he made on the cadaver he was unable to produce the dislocation by direct thrust except where the injury was so severe as to fracture the pelvis or break the ligaments. I do not think he would deny that dislocation could be produced in such a case as Dr. Cheever has described, in which I believe there was concomitant fracture of the pelvis.

Dr. Cheever: No.

Dr. Lund: Allis found that the only way he could produce a dorsal dislocation on the cadaver was by firm twisting, flexion of the leg and twisting it inward, carrying the knee inward and the foot outward, the opposite of the maneuvre which he proposes for reduction; this carries the head of the femur firmly against the posterior part of the capsule and bursts it. I have done this in one instance on the cadaver.

In regard to the inward dislocation, Allis has shown that that inward dislocation can be produced by direct leverage; that is, if the leg is taken and carried out from the body until the heel almost touches the ear, the great trochanter comes against the brim of the pelvis, and using the acetabulum as a bony lever the head of the bone is pried out. This Dr. Warren and myself have also verified on the cadaver.

Dr. Harrington: We do not get dislocations of the hip very often. I have had two, both in muscular subjects, both forward dislocations, very easily reduced by the Bigelow method. Does Dr. Allis claim that his method will be more uniformly successful than the Bigelow method? I would like to ask Dr. Warren how he would determine in what portion of the capsule the tear was when it was torn off as a cap.

Dr. Warren: I should think that would depend on the difficulties you had in reduction; if you pried the head of the bone from the dorsum towards the acetabulum and it would not stay, then you would have to work on that theory. I do not advocate this method of Allis as superior to Dr. Bigelow's. At the same time it was a very interesting study of the subject, and Allis has shown great ingenuity and mechanical knowledge in working out this problem, and I thought possibly if the surgeons were familiar with that they might have an opportunity to try it on a case, and then they could judge whether it was better or not. I should think it was well worth a trial.

Dr. F. B. Lund read a paper on

A CASE OF PERFORATING GASTRIC ULCER; OPERATION; RECOVERY.[1]

Dr. H. F. Hewes: I remember one case of gastric ulcer operated upon for perforation which illustrated a point in the diagnosis of the position of the ulcer of considerable interest, and I should think importance, to surgeons in considering the question of operation for removal of the ulcer. When, by a change of the position of the body, the ulcer is brought above the level of the gastric contents, the pain, which is a prominent symptom, vanishes. A patient, for instance, who has pain when lying down and not when standing up probably has an ulcer on the lesser curvature or in the region of the cardia. One in whom pain disappears on the right side and comes back on the left probably has ulcer in the region of the cardia, etc. This case had a very constant history of relief of pain when she stood up, and when she lay on the right side; at other times the pain was pretty constant. The ulcer was in an unusual position, but one borne out by the symptoms; it was in the fundus of the stomach, posterior wall, very close to the cardia, a most unusual place for an ulcer, but it bore out this point in the diagnosis very perfectly. I have not been able to test this point in diagnosis in other cases in which I have made notes, because the cases have not come to operation or autopsy.

Dr. Munro: I think the incision low down is important. I recall one case which came to operation on the third day, in which the ulcer could not be closed nor even stitched to the abdominal wall. It was walled off with gauze and tubes, etc. The patient lived three or four days comfortably, and then suddenly developed sepsis and died in twenty-four hours. Autopsy showed that the pelvis had not been thoroughly washed out at time of operation. Secondary sepsis developed from that focus, everything else in the abdomen and about the ulcer being sweet and clean. I feel sure if I had made Dr. Lund's second incision and thoroughly washed out the pelvis, she would have gotten well.

Dr. Elliot: I have had the good fortune to have the closed ulcer heal in all my cases. The patients have died from something else usually, confirming Dr. Lund's point that if you simply had the problem of sewing up the hole in the stomach or intestine, and nothing else to deal with, it probably would be a pretty successful thing, but infection and various other causes have come in to make my cases fatal.

My first case was a case of recurring hemorrhage of the stomach lasting for weeks and months, and finally I operated in profound anemia; that patient died from anemia, without any leak of stomach contents, although part of the stomach was resected.

In another case of perforation of the duodenum the incision was made from the ensiform cartilage to the symphysis pubis and the ulcer was stitched with a great deal of difficulty behind the duodenum. In that case we sewed up the abdominal wound very rapidly, as the patient was in a collapse, and the patient died of hemorrhage from one of the vessels in this long incision, the house officer not recognizing the trouble in time to secure the vessel. The ulcer was found to be perfectly closed.

Another case of ulcer of the duodenum was rather

[1] See page 25 of the Journal.

interesting from its symptoms. It occurred in a neurasthenic man whom no one would believe when he claimed to have pain. On the fifth day I was called to see him and operated. In this case the interesting symptom was present of entire absence of liver dulness, the gas having pumped itself out of the duodenum. The ulcer had formed a valve-like joint, so that the gas had leaked through, but no feces, as far as I could see. The ulcer was stitched, but the man died on the third or fourth day. At the autopsy it was found that although the ulcer had united well, there was a fine line of infection leading down beside the spine into the pelvis; the infection had undoubtedly taken place before the operation and drainage of the pelvis might have saved the patient. I usually drain the pelvis in such cases, but this case seemed to be without infection.

I am rather inclined to think that Dr. Lund's statistics and all the statistics on this subject are too favorable, since men report favorable cases more often than unfavorable. Still I think it is very encouraging to note the improvement shown year by year, and his case is certainly a very brilliant one.

DR. LUND: In regard to the diagnosis in these cases. In this case I stated that we made a diagnosis of probable perforation, but it was only a probable diagnosis. I was certain of general peritonitis, and was in doubt whether to incise over the appendix or epigastrium and was guided to the epigastrium by the greater tenderness there. Whether the perforation is to the right or to the left, Tinker has found in examining 213 cases that the tenderness is in the epigastrium and left hypochondrium. That was the case in this man although the perforation was to the right.

As to perforations on the posterior wall, these take place into the lesser peritoneal cavity necessarily, and it is therefore necessary to wash out the lesser peritoneal cavity. Several cases have been reported where that has been successfully done. In this case I could see through the lesser omentum that everything was clean, and there was no reason why anything should have got in there.

In regard to the cases where the patient has afterwards died of hemorrhage or perforation of another ulcer, it is important, where you have time, to look over the stomach and see whether there are other ulcers present, because not a few cases of this sort have been reported. In a good many cases it is inadvisable to do any more than to attend to the one you know to be the cause of perforation.

I think it is important to treat a man after you operate on him as you treat for gastric ulcer, and keep him on liquid diet a long time. It is somewhat remarkable that this man has had no dyspeptic symptoms since he left, and the completeness of the cure in his case may be partially due to his careful diet during his long stay in the hospital.

PATHOLOGICAL SPECIMEN.

DR. WARREN showed an ovarian tumor removed from a girl of sixteen. The tumor had been growing about six months. She had had no catamenia. At first it was thought to be a case of imperforate hymen, but examination under ether showed that that was not the case, but there was no cervix at all, no os apparently except a little dimple high above the pubes on the left-hand side. After the tumor was removed there was found to be an undeveloped uterus.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JANUARY 11, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE CASE METHOD OF TEACHING MEDICINE.

WE commend to the attention of those of our readers who are interested in medical education the communication by W. B. Cannon, printed in another part of this issue. It presents, to our mind, a perfectly feasible method of adding to the efficiency of clinical teaching, to the benefit not only of the student but also of the instructor. Mr. Cannon's paper is clearly the result of a very careful consideration of the merits and deficiencies of existing methods from the standpoint of a man who has himself had considerable experience in teaching as well as in being taught. We find little in the paper from which to dissent, and much which appeals to us as a distinct advance. Unlike many proposed reforms, it is not iconoclastic, but rather supplementary to what we already have, and what experience has shown to be on the whole serviceable. Recitations and even the much-abused didactic lecture are given a place, and the existing clinical lecture retains its position in the curriculum undisturbed. What Mr. Cannon would add to all this is a nearer personal contact with cases than is at present possible to the medical student under ordinary conditions. Since patients are unavailable for large classes in sufficient number, he thinks the same end may be at least partially attained by the study of cases as they have actually occurred and as they are transcribed in hospital or private record books. Let all the students of a class study the histories of actual cases and report upon them at stated conferences, using for purposes of study the various text-books at their command, and they will, in his opinion, come nearer to the practical problems of medicine than by the use of text-books without cases, or by the recitation method alone. The theory is, that a man who is capable of studying medicine at all is capable of facing the intricacies of clinical diagnosis at first hand, and not primarily through the medium of his instructor. He must be taught to be independent at the outset of his practical work, and this, it is urged, may be attained, in a measure at least, by the personal study of actual cases.

Cannon finds a strong argument for his idea in the success of a precisely similar system, now being used in connection with the study of law. This "case method" as it has been named, has led to the high position which the Harvard Law School holds in the teaching of law, and we quite agree with Cannon that there seems no reason why it should not apply with equal force to the study of clinical medicine. We at least feel sure that a careful reading of his paper will convince the most conservative of the reasonableness of his contention, which, as we understand it, is essentially that a student of medicine, like a student of any other branch of knowledge, needs above all things to be trained how to use his own mind, rather than to be overburdened merely with the results of others' learning. The case method as discussed in this paper seems to us to offer a possible solution of this problem, which with the growth of special knowledge is certainly assuming each year greater and greater significance.

SIR JAMES PAGET.

THE death of Sir James Paget recalls a period of English surgery when it occupied a position as high, if not higher, than that of surgery in any other country. Sir James's career began early in the century and he was already in his prime when Virchow was still a young man and enunciating his new ideas of cellular pathology, and Lister was practising surgery in Glasgow and still unknown to fame.

Paget's reputation both as a surgeon and a scientific man was based upon his lectures on "Surgical Pathology." This book, the first edition of which appeared in 1853, opened to the Anglo Saxon student a treasure house of surgical knowledge which gave inspiration to many a young surgeon to look beyond the mere mechanical side of his profession, and not to be satisfied with the crude description of disease which passed current in the text-books of the day. The technique of the microscopy of that time was still very crude and the knowledge which it yielded was known to but few. What Hyrtl afterwards called the kid glove work of the laboratory was then unknown, and to the student of to-day, accustomed as he is to instruments of precision like the modern microtome, to the intricacies of aniline stains and other refinements of the modern laboratory, Paget's workshop would have seemed a poor and humble source to have produced such far-reaching influences. Those, however, whose privilege it has been to know the man would not be surprised at the results he was able to obtain. An acute observer and a painstaking student, he possessed in an unusual degree the ability to express his thoughts in easy and elegant language, and it was at his lectures at St. Bartholomew's Hospital that the results of his investigations in pathology first took shape. He was as ready with his pen as with his tongue, and his colleagues to this day bear testimony to the facility with which, while surrounded by his family, he could quietly write out chapters which have since given him fame.

Those who have been brought up under the influence of the modern German school should not forget the scientific work of the English-speaking teachers of that time. They should realize that some of the impetus which is now being felt on the scientific side of medicine came from England, and that the work of Paget was presently followed by that of Lister.

Paget has also left his mark as clinician in his clinical lectures and essays. Although they were written before the antiseptic era had been firmly established they are replete with valuable information. Many of his expressions, such as the "nervous mimicry of disease," the "stammering of the bladder," "quiet necrosis," and other well-known phrases, are destined to hold their place in literature. His lecture on the "Calamities of Surgery" is one which every beginner should not fail to read. The name of Paget has not been as familiar to the student of the last decade of the century as it was before. The distinguished author had outlived most of his generation, and of late years had so far yielded to the pressure of the hand of time as to be unable to contribute to current literature or to continue to occupy a conspicuous position among his professional brethren. The International Medical Congress in London held in 1881 was probably one of his last public appearances before the medical world. For many years he had lived in the retirement which his brilliant work as a surgeon and a teacher had entitled him to enjoy.

MEDICAL NOTES.

THE PLAGUE SITUATION. — Bubonic plague is reported from the city and neighborhood of Sao Paulo, Brazil. In Honolulu, after a respite of thirteen days, several new cases have appeared, with three deaths. There is a tendency to evade the law with regard to death certificates and the authorities are thereby given considerable annoyance. One difficulty has been that the bodies of plague victims have in every case been cremated, which, through superstition, has led natives and Chinese to conceal their sick. Colonel Greenleaf cables from Manila that bubonic plague has appeared in and about Manila, in the Philippines. It is said that the disease carries off its victims within forty-eight hours from its attack, and in the country towns medical aid or supplies are not to be had readily, and then only in a limited way. Not only this, but burial of the corpses of those who have died from this disease is carelessly conducted, and absolutely no precautions are taken. The United States Government has taken prompt measures to prevent the possibility of the introduction of the disease into America. The quarantine of the Philippines will be in charge of the Marine-Hospital Service and special officers to manage the work will be detailed. Passed Assistant

Surgeon J. C. Perry, of the Marine-Hospital Service, has been appointed to have charge temporarily of the quarantine service at Manila. He has been at Hong Kong for six months, is familiar with other Asiatic ports and is regarded as an experienced and capable officer.

YELLOW FEVER IN CUBA. — The yellow-fever statistics for 1899 from Havana show that yellow fever is still to be reckoned with in Cuba. The report for December shows: New cases 70, deaths 22, recovered 30, under treatment 25. Of the patients, 23 were Americans and 50 Spaniards. Six of the former died and 10 of the latter. Experts hold that the difference in the ratio of deaths was due to the use of alcohol. Comparison of the whole year with the ten preceding years is favorable, but the last three months of 1899 were unfavorable. The December record of deaths from 1890 to 1899 is 11, 17, 32, 10, 24, 19, 225, 17, 13, 22. The yearly totals for the same period are 327, 363, 362, 512, 418, 560, 1,540, 1,056, 162, 103. It is of interest that the records show that, in spite of favorable weather since September 1st, the situation has been worse than during the corresponding period of the Spanish occupation. The explanation offered is the great influx of Spanish immigrants who were not acclimated and who were huddled in the lower quarters of the city. They were badly nourished and were unable to resist the disease. One prominent fact is the failure of house disinfection to kill the germs of the disease. Every house in the city has been disinfected several times. Those familiar with the conditions are not surprised at these facts. The introduction of proper methods of sanitation will no doubt gradually overcome the disease.

COMPETITION FOR THE AMERICAN MEDICAL ASSOCIATION MEDAL. — At the meeting of the American Medical Association held June 4, 1897, it was resolved to restore the former policy of the Association in favor of offering annually a gold medal for meritorious scientific work. The committee for this year consists of Drs. George M. Gould, of Philadelphia; E. Fletcher Ingals, of Chicago, and T. W. Huntington, of Sacramento, Cal. The competing essays shall be typewritten or printed and shall bear no mark revealing their authorship; but instead of the name of the author, there shall appear on each essay a motto, and accompanying each essay shall be a sealed envelope containing the name of the author and bearing on its outer surface the motto of identification. The committee shall have authority to reject and return all essays in case none have been found worthy of the Association medal. Competing essays must be in the hands of the committee not later than March 1, 1900. For further information address any member thereof.

DR. SCHENCK AND THE UNIVERSITY OF VIENNA. — It is reported that Dr. Schenck, who has of late come into particular prominence because of his theories regarding the determination of sex, has been removed from his position at the University, because of his radical views. He has had charge of the Institute for Embryology for the past twenty-six years.

WILLIAM A. HAMMOND, M.D. — Dr. William A. Hammond, former Surgeon-General of the U. S. Army, died in Washington, January 5th. He had conducted a sanitarium in Washington for some years immediately preceding his death.

PROFESSOR RÖNTGEN ACCEPTS CALL TO MUNICH. — Professor Röntgen, after considerable hesitation, has accepted a call to the University of Munich.

HOSPITALS FOR TUBERCULOSIS IN SPAIN. —It is said that two hospitals for the treatment of tuberculosis are about to be established in Spain.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, January 10, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 79, scarlatina 37, measles 73, typhoid fever 6.

SYSTEMATIC STUDY OF CANCER. — The fund of $100,000, less $8,000 legacy duty, left by Mrs. Caroline Brewer Croft has been turned over in part to Harvard University to be used for the purpose announced in the will. The money will be under the immediate jurisdiction of the Department of Surgery of the Harvard Medical School, which already has a small fund for purposes of research. Steps have been taken to begin the study for which the money was left. The principal appointee thus far is Dr. E. H. Nichols, who will sail for Europe early in February, to be gone two months, for the purpose of investigating the work heretofore done and at present being carried out in English and Continental laboratories. On his return the work will be vigorously prosecuted in those directions which promise hope of results.

AN EXORBITANT VERDICT SET ASIDE. — A verdict of $30,000 for a plaintiff in an accident suit against a railroad rendered some time ago has recently been set aside by Judge Bishop, of the Superior Court, and a new trial ordered unless a compromise can be reached. Excessive verdicts seem, on the whole, to be increasing in number; it is altogether to be commended that the judges at times take occasion to assert their authority in over-ruling unjust jury verdicts in these cases.

INCREASE IN CREMATIONS. — The sixth annual meeting of the Massachusetts Cremation Society has recently been held. The report showed that the increase in the number of cremations from year to year has been very pronounced. There were 230 in 1899 as compared with 167 the year before. The total number of cremations since the crematory was opened is 869. Officers were elected as follows: Clerk, John Homans, 2d; Treasurer, John Ritchie; Directors, James R. Chadwick, John O. Marble, Augustus Hemenway, Babson S. Ladd, Robert H. Richards, John

Ritchie, John Homans, 2d, John A. Higginson and Richard W. Hale.

No Plague in Boston Harbor. — The steamer *Fitz Clarence*, from Antwerp, was last week detained by the quarantine authorities for several days because of a suspicious case, which it was thought might be plague. Further investigation has shown that this is not the fact and the vessel with her cargo has been discharged from quarantine. The patient, who was a stowaway, will be returned to Antwerp, as the law demands.

Two Centenarians. — Mrs. Cynthia Conant, reported to be one hundred and one years old, died last week in Springfield, Mass. Lucy Boston, of Webster, Mass., said to have been one hundred and five years old, and the last survivor of the Nikmaunk tribe of Indians, was burned to death in her house, January 6th, the fire probably being the work of incendiaries.

The Will of R. B. Brigham. — The late Robert Brock Brigham, after bequeathing small sums to various charities, leaves the greater part of his estate to found a hospital in Boston for chronic disease, to be known as the Robert B. Brigham Hospital for Incurables. The estate is a large one.

Bequests to Hospitals. — The late Daniel Sharp Ford has left by will the following bequests to hospitals: Boston City Hospital, $6,000; Massachusetts General Hospital, $7,000; Children's Hospital, Boston, $5,000.

Lectures on the Evolution of Sex. — Prof. Patrick Geddes, of Edinburgh, is giving a course of lectures on the evolution of sex under the auspices of the Twentieth Century Club.

A Hospital for Jamaica Plain. — Mrs. Abby L. A. Faulker has bequeathed her entire estate to be used ultimately for the establishment of a hospital in Jamaica Plain.

NEW YORK.

Tenement Houses: State Commission in Lunacy. — In his second annual message to the Legislature, Governor Roosevelt urges that special attention be given to the need of reform in the laws governing tenement houses. The Tenement-House Commission of 1894, he says, declared that, in its opinion, the tenement-house laws needed to be revised every five years, and he believes that the improvements in building materials and construction of tenements and the advance in sanitary legislation all demand further modification of existing laws. To this end he suggests the appointment of a commission to present a revised code of tenement-house laws. He expresses his hearty sympathy with the objects sought in the drug clerks' bill presented last year, which owing to certain defects he was unable to sign, and trusts that a satisfactory bill may be found during the present session. In speaking of the work of the State Commission in Lunacy, he states that progressive improvement shows that the State care system was wisely founded and must remain the permanent policy of the State. Not only has the care of the insane been bettered, but the cost has been lessened. The accommodations have been increased and improved, and the annual increment of permanent cases, the ultimate cost of the State of each of which is computed at $5,000, has been diminished. While the reduction of cost of maintenance the past year from the per capita of $185.20 in 1898 to $178.42, in the face of a general advance in prices, and contrasted with $216 before the State Care Act, is satisfactory, it is of far more importance that the annual increase of patients in hospitals is steadily decreasing. In 1897 it was 733, in 1898, 634, and in 1899, 529. These figures allow but one conclusion — better care of the insane; and that conclusion is supported by the fact that 1,009 patients have been discharged fully recovered, while 921 others have been sufficiently improved to allow their return to their homes.

Academy of Medicine Free from Debt. — At a meeting of the New York Academy of Medicine held January 4th, Dr. Reginald H. Sayre, the Treasurer of the Board of Trustees, reported that the remaining indebtedness of the Academy, amounting to $2,000, for the erection of its present commodious building, had been paid, and that it would start in on the new year entirely free from debt. The building cost about $240,000, but with the increased valuation of the land since its purchase the property is worth very much more than that at the present time.

Death from Carbolic Acid. — A fatal accident of unusual character occurred at the City Hospital on Blackwell's Island on January 5th. A patient who was in a very unclean condition was being given a bath, and the male nurse who had charge of him poured over his head and body about eight ounces of a strong solution of carbolic acid, which he supposed to be tincture of larkspur. The poor man suffered intense agony and in spite of prompt treatment died within an hour from the result of the burns caused by the acid.

The Babies' Hospital. — The eleventh annual meeting of the managers of the Babies' Hospital, connected with the Post-Graduate Medical School, was held on January 4th. The institution has for some time been located in the fine building on Lexington Avenue, erected for a private hospital by Dr. T. Gaillard Thomas, and during the past year 394 patients were treated. Thirty-five beds are at present in use, and 24 nurses have been graduated from the training school connected with the hospital.

Officers of New York Neurological Society. — At the annual meeting of the New York Neurological Society held January 2, 1900, the following officers were elected for the coming year: President, Frederick Peterson, M.D.; 1st Vice-President, Joseph Collins, M. D.; 2d Vice-President, L. Stieglitz, M.D.; Recording Secretary, Pearce Bailey, M.D.; Corresponding Secretary, Lewis A. Conner, M.D.; Treasurer, Graeme

M. Hammond, M.D.; Councillors, C. L. Dana, M.D., M. A. Starr, M.D., B. Sachs, M.D., E. D. Fisher, M. D., J. Arthur Booth, M.D.

SOCIETY FOR THE RELIEF OF WIDOWS AND ORPHANS OF MEDICAL MEN. — This Society, instituted in 1842, has recently issued its fifty-eighth annual statement. During the time of its existence it has assisted a large number of widows and orphans. In the last year it has aided eighteen widows and six children of deceased members. The members of the Society now number one hundred and thirty-seven.

A NEW STORAGE RESERVOIR. — A proposition for the construction of a new storage reservoir in Westchester County, in connection with the Croton system, of the capacity of 9,000,000,000 gallons, which was made some time ago by Commissioner Dalton, of the Department of Water Supply, has now been adopted by the Board of Public Improvements.

BEQUESTS BY E. F. HOLDEN, M.D. — Erastus F. Holden, who died recently at Syracuse, N. Y., bequeathed $25,000 to Syracuse University and $5,000 to the Syracuse Women and Children's Hospital.

CENTENARIAN. — Mrs. Sarah Allen, who is a native of Ireland, celebrated her one hundredth birthday on January 1st, at Union Hill, near Hoboken.

ARMY NOTES.

UNITED STATES REPRESENTATIVES TO INTERNATIONAL MEDICAL CONGRESS. — The President has designated the following officials to represent the United States Government at the International Medical Congress, which meets in Paris on August 2d, next, and at the Congress of Hygiene and Demography, which assembles at the same place on August 10th: For the army, Surgeon-General Sternberg and Major LaGarde; for the navy, Surgeon-General Van Reypen; for the Marine-Hospital Service, Surgeon-General Wyman and Passed Assistant Surgeon Rosenau. Major LaGarde has been invited to read a paper on gunshot wounds, the discussion to be opened by the Surgeon-General of the Austro-Hungarian Army.

MEDICAL ASSISTANCE TO THE ISLAND OF GUAM. — Flattering reports have reached this country concerning the efficient services rendered on the Island of Guam by Surgeons Leech, Stone and Grunwell, U. S. Navy. On occupation by United States forces this island was found to be entirely without medical assistance, the Spanish physicians having all taken their departure. In addition to the performance of their duties on board the naval vessels at the Guam station the gentlemen above named have been indefatigable in their work of caring for the sick, establishing hospitals and endeavoring to disseminate a knowledge of elementary hygiene among the people at large; their work being greatly appreciated by the natives.

ASSOCIATION OF SPANISH WAR VETERANS. — Major Victor C. Vaughan, U. S. V., has been recently appointed Surgeon-General of the Association of Spanish War Veterans. Major Vaughan is well-known to the profession as professor of hygiene at the University of Michigan, to which position he returned some months ago. Major Vaughan was commissioned as surgeon of the 33d Michigan Volunteers and accompanied that regiment to Cuba, being present during the operations against Santiago. He was subsequently made a chief surgeon of division, and for many months was a member of the board appointed to investigate the typhoid epidemics in the army camp.

A BED FIELD HOSPITAL FOR SOUTH AFRICA. — It is understood that the organization and equipment of a three-hundred-bed field hospital, for service with the British forces in South Africa, is being projected by the same organization of American women in England by which the hospital ship *Maine* was fitted out. As it is contemplated that this hospital shall be complete in its organization, personnel and equipment, even to possessing its own transportation and commissariat, it is evident that the problem presented is much more difficult of solution than the organization of a hospital ship.

SMALL-POX CAMP, ANGEL ISLAND. — The small-pox camp established on Angel Island, in San Francisco Bay, which has been maintained during the past two months on account of an outbreak of this disease in a negro volunteer regiment, has been recently broken up, twenty-three patients being returned to duty.

SAILING OF THE "MISSOURI." — The hospital ship *Missouri* has recently sailed from Manila for San Francisco with 286 sick and wounded on board.

Miscellany.

LUTHER D. WOODBRIDGE, M.D.

AT a meeting of the Berkshire District Section of the Massachusetts Medical Society, held in Pittsfield, December 28, 1898, it was unanimously ordered that the following notice as a memorial of Dr. Luther Dana Woodbridge be placed upon the records of the Society; that a copy be sent to the family, and that copies be furnished to the *Boston Medical and Surgical Journal* and to the North Adams and Pittsfield papers, for publication:

Dr. Luther D. Woodbridge, of Williamstown, died suddenly from heart disease on November 3, 1899. In his death the Berkshire District Medical Society has suffered a severe loss, for he was one of the most esteemed and gifted of our members.

Dr. Woodbridge was born at Perth Amboy, N. J., December 27, 1850; was graduated at Williams College in 1872, and the College of Physicians and Surgeons, New York, in 1877. Before entering upon his medical studies he was a tutor at Roberts College, Constantinople, and afterwards instructor in gymnastics at Williams College. After receiving his medical degree, he served as interne at Roosevelt Hospital and as Clinical Assistant at Chambers Street Hospital, New York, after which he spent a year in the hospitals of Vienna and London. In 1881 he began

practice in New York and received an appointment as assistant surgeon to the Manhattan Eye and Ear Hospital. In 1884 he was chosen professor of anatomy, physiology and hygiene at Williams College, which position he has ever since filled with marked ability and success, at the same time practising medicine in Williamstown. He became a member of the Massachusetts Medical Society in 1888, was president of the Berkshire District Medical Society in 1893, and of the North Berkshire Medical Society in 1889; he was a member of the American Medical Association and of the American Academy of Medicine, and in 1894 was appointed lecturer on diseases of the nervous system in the College of Physicians and Surgeons, Boston.

He was a regular attendant at the meetings of the Berkshire District Medical Society, and added greatly to their interest by his instructive addresses and his thorough and scientific methods of study. Always courteous and dignified in manner, he had yet great independence of thought and utterance, and his fellow members could not fail to be impressed with his ability, his sincerity and his elevated standards, both intellectual and moral. As a medical practitioner he was deservedly successful, and he was greatly beloved and respected, as he is now deeply mourned, by the whole of the highly cultured community in which he lived. Having begun life with missionary work, he never abandoned that vocation, but always labored zealously and effectively for the spiritual as well as the physical welfare of his fellowmen.

The Fellows of this Society tender to his bereaved family their sincere sympathy in their great affliction.

W. W. SCOFIELD, *President*; L. C. SWIFT, *Secretary*, of the Berkshire District Medical Society.

WAR NOTES FROM SOUTH AFRICA.

A CORRESPONDENT of the *British Medical Journal* speaks of the Mauser and Lee-Metford bullets, in use in the South African War, as follows:

"A wounded Boer referred to the Lee-Metford as a 'gentlemanly bullet,' and this remark is equally applicable to the Mauser. The wounds made by them are small, clean, and little disposed to suppurate, and the tendency to suppuration is no doubt decreased by the excellent physical condition of the patients and the healthiness of the district. Shock as a sign has been conspicuous by its absence even in the most serious cases, and gives little or no aid in the diagnosis of visceral injury. Retained bullets are comparatively uncommon, no doubt on account of the fact that most of the men have been wounded in rapid advances. The bullets met with have been little deformed, unless they have struck stones before entering, and I have seen no single instance which would suggest the use of either flattened or so-called explosive bullets among the wounded here. The only large exit wounds have been one or two opposite comminuted fractures."

It is worthy of remark, as in our own recent war, that the number of operations is relatively few. Speaking of this, the correspondent, G. H. Makins, F. R. C. S., says:

"Operations at the field hospitals have been very few in number; I think, at the most, six amputations have gone down to Wynberg, and there can be little doubt that such operations will be comparatively infrequent in this series of cases. The cases, as a whole, started remarkably well. There has been no serious wound infection up to the present — a great tribute to the care with which the dressings have been applied in the hospitals and on the field by the hard-worked officers of the R. A. M. C. In this camp, during the last week, on several occasions the officers were up all night, or went to bed at 12, to rise at 4 A. M. The heat during the day has been very great, 108° to 115° F. in the bell tents in the afternoons of the last few days."

Correspondence.

THE BEST DIET FOR THE TROPICS — THE ARMY RATION.

SAN JUAN, PUERTO RICO, December 27, 1899.

MR. EDITOR: — As a supplement to the article of my scientific friend, Colonel Smart, on the "Army Ration," let me add a few practical observations gathered in Puerto Rico.

Duty has taken me at one time or another since the first days of the American invasion into almost every town from Ysabela on the northwest coast to Humacao on the east coast, and then up the military road to this capital. In the district of Guayama and Southern Humacao it was part of my business to investigate the cause of deaths among the natives.

Everywhere I found the main causes assigned to be anemia and phthisis. Everywhere I went I was struck by this ever-prevalent anemia. The pale, yellowish, waxy skin, bloodless lips and swollen, puffy features formed a picture never seen by me out of tropical Puerto Rico. Yet I soon found that these people had been living on rice, beans, maize, dried codfish and fruits. Meat very rarely entered into their diet. They and their fathers before them had lived exclusively on the diet urged by the public press as suitable for tropical climates, and the result filled the hospitals with such ghastly cases of anemia that no one who has once seen the picture can ever forget the impression. On the other hand, I soon discovered that the people who lived in the towns and could afford it ate two hearty meals daily. These people, I believe, used more meat than we used in American cities, and there is no doubt in my mind but that I have used more meat and felt more need for it since I have been here than I ever used in the same time in the United States. Yet I am one of the few that have not had to go home for ill health; while the natives that eat in the hotels with me, and as freely as I do, are perfectly healthy individuals who showed not the least trace of anemia.

Only a few days since a native informed me with much gusto that one of the best things that Puerto Rico afforded was *chuleta de cerdo* — pork chops — surely one of the most unsuitable articles of diet for a tropic climate, as our physiological friends will tell us, and yet the absence of which, in my opinion, made that native anemia to a noticeable degree.

These observations are so common in this climate, and have been so forcibly impressed on me, that I feel more and more the wisdom of going very, very slowly in urging alterations in the ration.

Very respectfully,
P. R. EGAN, M.D.,
Assistant Surgeon, U. S. Army.

"TAKE NO THOUGHT."

BALTIMORE, MD, January 6, 1900.

MR. EDITOR: — The following extract from Morley's "Oliver Cromwell," *Century* for December, page 277, seems applicable to your criticism of Dr. Osler's McGill University Address: "In other words, Cromwell fixed his eyes upon the need of the hour, used all his energy and devotion in meeting it and let that suffice. In men of action there are few better marks of a superior mind."

Very truly yours,
EUGENE F. CORDELL, M.D.

METEOROLOGICAL RECORD

Deaths reported 2,496; under five years of age 744; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping-cough, erysipelas and fevers) 261, acute lung diseases 459, consumption 352, diphtheria and croup 106, typhoid fever 32, measles 31, scarlet fever 29, diarrheal diseases 22, whooping-cough 18, cerebrospinal meningitis 12, erysipelas 11.

From measles New York 20, Providence 7, Washington 2, Boston and Springfield 1 each. From diarrheal diseases New York 10, Cincinnati 3, Baltimore, Providence and Fall River 2 each, Nashville, Worcester and Holyoke 1 each. From whooping-cough New York 12, Baltimore 2, Boston and Cambridge 1 each. From cerebrospinal meningitis New York 5, Boston and Worcester 2 each, Lawrence Gloucester and Newton 1 each. From erysipelas New York 8, Cincinnati 2, Holyoke 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,404,408, for the week ending December 23d, the death-rate was 27.5. Deaths reported 6,061: acute diseases of the respiratory organs (London) 968, measles 168, diphtheria 122, whooping-cough 111, fever 80, diarrhœa 45, scarlet fever 44, small-pox (Hull) 8.

The death-rates ranged from 17.6 in Huddersfield to 42.4 in Portsmouth: Bradford 21.0, Cardiff 24.4, Gateshead 21.0, Hull 23.1, Leeds 18.9, Liverpool 33.9, London 29.9, Manchester 23.8, Newcastle-on-Tyne 24.9, Nottingham 25.3, Plymouth 38.9, Salford 26.8, Sheffield 24.0, Sunderland 29.4, West Ham 20.7.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 6, 1900

A. W. DUNBAR, passed assistant surgeon, ordered to duty on the "Monongahela" immediately.

R. K. SMITH, passed assistant surgeon, detached from the Naval Hospital, Mare Island, Cal., on reporting of relief and ordered to duty on the "Pensacola."

J. H. PAYNE, assistant surgeon, detached from the "Indiana" and ordered to duty at the Naval Hospital, Mare Island, Cal.

A. F. PRICE, medical director, promoted to medical director from April 9, 1899.

G. M. PICKRELL, surgeon, promoted to surgeon from September 19, 1899.

R. SPEAR, assistant surgeon, ordered to duty in connection with the Naval Recruiting Rendezvous, Philadelphia, Pa., January 9th.

I. N. HURD, pharmacist, ordered to duty at the Key West Naval Station, January 11th.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE FOURTEEN DAYS ENDING JANUARY 4, 1900

SAWTELLE, H. W., surgeon. Granted leave of absence for thirty days. December 28, 1899.

MCINTOSH, W. P., surgeon. Granted leave of absence for five days. December 27, 1899.

PERRY, J. C., passed assistant surgeon. To proceed to Amoy, China, for special temporary duty. December 27, 1899.

ROSENAU, M. J., passed assistant surgeon. To proceed to Baltimore, Md., for special temporary duty. December 23, 1899.

THOMAS A. R., passed assistant surgeon. To proceed to New York, N. Y., and report to Surgeon L. L. WILLIAMS (Immigration Depot) for special temporary duty. December 22, 1899. To proceed to Rotterdam, Netherlands, for duty. December 22 1899.

COFER, L. E., assistant surgeon. Granted leave of absence for one month. December 23, 1899.

TABB, S. R., assistant surgeon. Granted leave of absence for fifteen days. December 27, 1899.

DUFFY, FRANCIS, acting assistant surgeon. Granted leave of absence for seven days. December 28, 1899.

MCINTOSH, W. P., surgeon. To proceed to Columbia, Tenn., for special temporary duty. January 2, 1900.

PERRY, J. C., passed assistant surgeon. To proceed to Manila, Philippine Islands, for temporary duty. January 4, 1900.

FRICKS, L. D., assistant surgeon. Assigned to duty as assistant to the director of the Hygienic Laboratory, Washington, D. C. January 4, 1900.

MOORE, DUNLOP, assistant surgeon. Relieved from duty at San Francisco, Cal., and directed to proceed to Portland, Ore., and assume command of the Service. December 29, 1899.

CURRIE, D. H., assistant surgeon. Relieved from duty at Louisville, Ky., and directed to proceed to Washington, D. C., and report to the director of the Hygienic Laboratory for temporary duty. December 29, 1899.

SOCIETY NOTICE.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The Section for Clinical Medicine, Pathology and Hygiene will hold its meeting at 19 Boylston Place, Wednesday, January 17, 1900, at 8 P. M.

At 8 o'clock: Dr. E. W. Taylor will report "An Unusual Complication of Epilepsy."

At 8.15 o'clock: Dr. H. F. Hewes will read a paper entitled "Some Observations upon Diseases of the Stomach." Discussion by Drs. E. G. Cutler and E. P. Joslin.

J. BERGEN OGDEN, M.D., *Secretary*,
Harvard Medical School, Boston.

RECENT DEATH.

CHARLES KINGSLEY, M.D., M.M.S.S., died in Marlboro, December 29, 1899, aged thirty years.

Original Articles.

A RHODE ISLAND PHILOSOPHER (ELISHA BARTLETT).[1]

BY WILLIAM OSLER, M.D.,
Professor of Medicine, Johns Hopkins University, Baltimore, Md.

Rhode Island can boast of one great philosopher, one to whose flights in the empyrean neither Roger Williams nor any of her sons could soar, but the immortal Berkeley was only a transient guest in this State, waiting quietly and happily for the realization of his Utopian schemes. Still he lived long enough in Rhode Island to make his name part of her history; long enough in America to make her the inspiration of his celebrated lines on the course of empire. Elisha Bartlett, teacher, philosopher, author, of whom I am about to speak, whom you may claim as the most distinguished physician of this State, has left no deep impress on your local history or institutions. Here he was born and educated and to this his home he returned to die, but his busy life was spent in other fields, where to-day his memory is cherished more warmly than in the land of his birth.

I.

Born at Smithfield in 1804, Bartlett was singularly fortunate in his parents, who were members of the Society of Friends, strong, earnest souls, well endowed with graces of the head and of the heart. The gentle life, the zeal for practical righteousness and the simplicity of the faith of the followers of Fox, put a hall-mark on the sensitive youth which the rough usage of the world never obliterated. No account of Bartlett's early life and school-days exists — an index that they were happy and peaceful. We may read in his poem called "An Allegory" certain autobiographical details, transferring the

> "Meadow and field, and forest, dale and hill;
> Orchards, green hedgerows, gardens, stately trees,"

from the old England which he describes to the banks of Narragansett Bay. Paraphrasing other parts of the poem we may say that auspicious stars shone over his cradle with the kindliest light and promise, and amid the genial air of a New England home, goodness, truth and beauty were his portion. He tells of the wonder and delight stirred in his young soul by the thousand tales of "fairies and genii, giants, dwarfs and that redoubtable and valiant Jack who slew the giants." Then as the days lengthened he came under the spell of "The Arabian Nights" and of "Robinson Crusoe." Looking back in after years he compared this hearty, wholesome life to some bounteous spring that wells up from the deep heart of the earth. Addison, Goldsmith and Washington Irving filled his soul with freshness like the dawn,

> "And led by love and kindness, ran the hours
> Their merry round till boyhood passed away."

In the ruder discipline and strife of school and college he grew to manhood with (as he expressed it) "a fine free healthfulness," and with faculties self-poised and balanced.

At Smithfield, at Uxbridge, and at a well-known Friends' institution in New York, Bartlett obtained a very thorough preliminary education. Details of his medical course are not at hand, but after studying with Dr. Willard, of Uxbridge, Drs. Greene and Heywood, of Worcester, and Dr. Levi Wheaton, of Providence, and attending medical lectures at Boston and at Providence, he took his doctor's degree at Brown University in 1826, a year before the untimely end of the medical department.[2]

In June, 1826, Bartlett sailed for Europe, and the letters to his sisters, which, with other Bartlett papers, have been kindly sent me by his nephew, the Hon. Judge Bartlett, of the New York Court of Appeals, give a delightful account of his year as a student abroad. He remained in Paris until December; then, in company with his fellow-student, Dr. Southwick, he visited the chief cities of Italy, returning to Paris early in March. The month of May, 1827, was spent in London, and he sailed from Liverpool June 8th. Unfortunately the letters to his sisters contain very few references to his medical studies, but I have extracted a few memoranda from them.

Writing August 24, 1826, he says: "The celebrated Laennec died at his country residence on the 13th of the present month. The publication in 1819 of a new method of ascertaining diseases of the chest forms an era in the history of medicine. M. Laennec fell a victim to one of those diseases the investigation of which by himself has enriched the field of science, contributed to the alleviation of human suffering, and given his own name a high rank among the great and the good men of his age." He asked that this memorandum should appear in the Providence papers.

Writing September 4th, he speaks of attending every day at the Jardin des Plantes to hear the lectures of Cloquet and Cuvier.

One of the professors at the medical school, he says, looked more like a jolly stage driver or a good-natured, blustering butcher than anything else. "He lectures sometimes standing, and sometimes leaning against a post, or straddling over a high stool, flourishing a lancet in one hand and a snuff-box in the other, on the contents of which he is continually laying the most inordinate contributions. He wears during the time an old rusty looking black cap. The familiarity of the distinguished surgeons and physicians with their students struck me at first sight very forcibly, being in such perfect contrast to the proud port and haughty carriage of some of our New England professors. I wish they might step into the Hôtel Dieu and La Charité and take a lesson or two of Boyer and Dupuytren, barons of the Empire, and two of the most distinguished surgeons in the world."

In the letter of October 10th he says, "The public lectures opened this week, and we are continually engaged from half-past six in the morning till bedtime. Visits are made at all the hospitals by candle-light, and a lecture delivered at most of them immediately after the visit."

He speaks of attending the lectures of Geoffroy St. Hilaire, who, he says, "lectures very badly; his ges-

[1] An address delivered before the Rhode Island State Medical Society, December 7, 1899.

[2] Parsons closes his *Historical Tract on the Brown University Medical School* with the sentence, "Whether this city, the second in New England, shall become the seat of such a school (that is, a revived department of medicine) must depend very much on the zeal, persistence and ability of its physicians." May I be permitted to remark, Mr. President, that the existing conditions are singularly favorable for a small first-class school. Here are college laboratories of physics, chemistry and biology, and here is a modern hospital with one hundred and fifty beds. What is lacking? Neither zeal, persistence nor ability on the part of the physicians, but a generous donation to the University of a million of dollars with which to equip and endow laboratories of anatomy, physiology, pathology and hygiene. These alone are lacking; the preliminary scientific school is here; the clinical school is at your doors; the money should be the least difficult thing to get in this plutocratic town. The day has come for small medical schools in university towns with good clinical facilities.

tures, though he is a Frenchman, are exceedingly awkward, and he has a sing-song tone like that which one often hears in a Methodist or Quaker preacher."

Bartlett probably acquired in Paris the three principles which Oliver Wendell Holmes said that he had learned: "Not to take authority when I can have facts; not to guess when I can know; not to think a man must take physic because he is sick."[3]

Strangely enough I find no reference in these Paris letters to the man of all others who influenced Bartlett most deeply. In Louis, even more than in Laennec, the young American students of that day found light and leading. The numerical method, based on a painstaking study of all the phenomena of disease in the wards and in the dead-house, appealed with peculiar force to their practical minds, and Louis's brilliant observations on phthisis and on fevers constituted, as Bartlett remarked, a new and great era in the history of medical science. I cannot find any definite statement of Bartlett's relations with Louis in 1826–27, at which period the latter was still working quietly at La Charité. His monograph on phthisis had been published in 1825, and had at once given him a reputation as one of the great lights of the French school. He was at this time very busy collecting material for his still more important work on typhoid fever, and it is scarcely possible that Bartlett could have frequented La Charité without meeting the grave, unobtrusive student, who, with note-book in hand, literally lived in the wards and in the dead-house. Secluded from the world, living as a voluntary assistant to Chomel in this quiet haven of observation, apart from the turbid seas of speculation which surged outside, Louis for seven years pursued his remarkable career. Whether or not Bartlett came into personal contact with him at this time cannot be decided. However this may be, subsequently the great French clinician became his model and his master, and to him he dedicated his first edition of the "Fevers," and his "Essay on the Philosophy of Medical Science."

For a young man of twenty-two, these letters — written offhand — show an unusually good literary style, and many incidental references indicate that he had received a general education much above the average. The strong Christian spirit which he felt all through life is already manifest, as may be gleaned from one or two expressions in the letters. Writing September 4, 1826, to his sisters, he refers to the death of a dear friend and her little sister. "There is a cheering consolation in the reflection that 'of such is the kingdom of heaven,' and that their spirits have gone in perfect and sinless purity to their home of bliss, and we may believe that they in their turn have become guardian angels to those who cherished and protected them here:

> 'They were their guardian angels here,
> They guardian angels now to them.'"

In 1827, shortly after completing his twenty-third year, Bartlett settled at Lowell, then a town of only 3,500 inhabitants, but growing rapidly, owing to the establishment of numerous mills. This was his home for nearly twenty years, and to it, and later to Woonsocket, he returned in the intervals between his college work in different sections of the country. As Dr. D. C. Patterson remarks, "He became at once the universal favorite, and began to take a deep interest in the physical welfare of the townsmen." In 1828 he delivered lectures before the Lowell Lyceum on contagious diseases, and he gave frequent popular lectures on sanitation and hygiene. In 1828 he was the orator on the Fourth of July. In 1836 he delivered a course of popular lectures on physiology.

Evidently Bartlett had the "grace of favor" in a remarkable degree. Bishop Clark pictures him in those days in the following words: "Some twenty-five years ago, I used to meet a young man in the town of Lowell, whose presence carried sunshine wherever he went; whose tenderness and skill relieved the darkness of many a chamber of sickness, and whom all the community were fast learning to love and honor. Life lay before him, full of promise; the delicate temper of his soul fitting him to the most exquisite enjoyment of all the pure delights of nature, and his cheerful temperament giving a genial and generous glow to the refined circles of which he was one of the chiefest ornaments."

When only thirty-two, before he had been in Lowell ten years, he was elected by a respectable majority as the first mayor of the city, and he was re-elected the following year. A letter from the Hon. Caleb Cushing, dated April 20, 1841, gives us an idea of the estimate which a clear-headed layman placed upon him. "Dr. Bartlett enjoys in the city of Lowell the unqualified respect of that community, and its affectionate esteem,— respect and esteem due alike to his public relations to that city, as formerly its popular and useful chief magistrate, and at all times one of its most patriotic and valued citizens; to his unblemished integrity of character and amenity of deportment; to his eminence in his profession; to the endearments of private friendship; and in general to his talents, accomplishments, manners and principles."

To two interesting episodes in his life at Lowell I may refer at greater length. The rapid growth of the industries in Lowell had brought in from the surrounding country a very large number of young girls as operatives in the mills, and their physical and moral condition had been seriously impugned by writers in certain leading Boston papers. These charges were investigated in a most thorough way by Bartlett, who published in the *Lowell Courier* in 1839, and republished in pamphlet form (1841) his well-known "Vindication of the Character and Condition of the Females Employed in the Lowell Mills." This is a very strong paper, based on careful personal investigations, and really proved to be what the title indicated. It did not, however, escape without adverse criticism, and among the Bartlett papers there is a review of the "Vindication" by a citizen of Lowell in 1842, which presents the other side of a picture, by no means a pleasant one, of the prolonged hours of the operatives and their wretched life in boarding houses.

One of the most interesting incidents of his life at this period was the reception to Dickens, whose visit to Lowell occurred during Dr. Bartlett's mayoralty. In the "American Notes" Dickens speaks of the girls as "healthy in appearance, many of them remarkably so, and had the manners and deportment of young women, not of degraded brutes of burden." Oliver Wendell Holmes says, referring to this occasion: "I have been told a distinguished foreign visitor (Charles Dickens), who went through the whole length and breadth of the land, said that of all the many welcomes he received from statesmen renowned as orators, from men whose profession is eloquence, not one was so

[3] Morse's Life, vol. i, p. 109.

impressive and felicitous as that which was spoken by Dr. Bartlett, then mayor of Lowell, our brother in the silent profession, which he graced with these unwonted accomplishments."

In 1840 he was elected to the Legislature of the State of Massachusetts and served two terms. In 1845 he was nominated by the Governor a member of the Board of Education of the State in the place of Jared Sparks. Holmes, who was familiar with Bartlett at this period of his career, has left on record the following charming description: "It is easy to recall his ever-welcome and gracious presence. On his expanded forehead no one could fail to trace the impress of a large and calm intelligence. In his most open and beaming smile none could help feeling the warmth of a heart which was the seat of all generous and kindly affections. When he spoke his tones were of singular softness, his thoughts came in chosen words, scholar-like, yet unpretending, often playful, always full of lively expressions, giving the idea of one that could be dangerously keen in his judgments, had he not kept his fastidiousness to himself, and his charity to sheathe the weakness of others. In familiar intercourse — and the writer of these paragraphs was once under the same roof with him for some months — no one could be more companionable and winning in all his ways. The little trials of life he took kindly and cheerily, turning into pleasantry the petty inconveniences which a less thoroughly good-natured man would have fretted over."

II.

For many years there was in this country a group of peripatetic teachers who, like the Sophists of Greece, went from town to town, staying a year or two in each, or they divided their time between a winter session in a large city school and a summer term in a small country one. Among them Daniel Drake takes the precedence, as he made eleven moves in the course of his stirring and eventful life. Bartlett comes an easy second, as he taught in nine schools. Dunglison, T. R. Beck, Willard Parker, Alonzo Clark, the elder Gross, Austin Flint, Frank H. Hamilton and many others whom I could name, belonged to this group of wandering professors. The medical education of the day was almost exclusively theoretical; the teachers lectured for a short four months' session; there was a little dissection, a few major operations were witnessed, the fees were paid, examinations were held, and all was over. No wonder, under such conditions, that many of the most flourishing schools were found amid the sylvan groves of small country towns. In New England there were five schools in small towns, and in the State of New York the well-known country schools at Fairfield and Geneva. As there was not enough practice in the small places to go round, the teachers for the most part stayed only for the session, at the end of which it was not unusual for the major part of the faculty, with the students, to migrate to another institution, where the lectures were repeated and the class graduated. T. R. Beck's introductory lecture, in 1824, at Fairfield, "On the Utility of Country Medical Institutions," pictures in glowing terms their advantages. One sentence brought to my mind the picture of a fine old doctor, on the Niagara peninsula, a graduate of Fairfield, who possibly may have listened to the very address. Dr. Beck asks: "What is the clinical instruction of the country student? It is this — after attending a course of lectures on the several branches of medicine and becoming acquainted with their general bearing, he during the summer repairs to the office of a practitioner; attends him in his visits to his patients; views the diseases peculiar to the different districts; observes the treatment that situation or habits of life indicate and from day to day verifies the lessons he has received. Here, then, is a direct preparation for the life he intends to pursue." And I may say that it was just this training that made of my old friend one of the best general practitioners it has ever been my pleasure to know.

In the letters we can follow Bartlett's wanderings during the next twenty years, from the time of his appointment to one of the smallest of the schools to his final position as one of the chief ornaments of the leading school of New York. In 1832 he held his first teaching position, that of professor of pathological anatomy and of materia medica in the Berkshire Medical Institute, at Pittsfield. The following is an extract from a letter to Dr. John Orne Green, dated Pittsfield, November 25, 1833: "The character of the class is said to be superior even to that of last year. We have a large number of excellent students. Parker is as popular as ever, and Professor Childs has the credit of having improved very much in his manner of teaching. The members of the class are attentive to their studies, eager for knowledge, and regular in their attendance on the lectures. I have lectures, most of the time, twice a day, at 10 A. M. and at 2 P. M. I shall finish my course on materia medica by the middle of this week, and the remainder of my time will be occupied with lectures of medical jurisprudence and pathological anatomy. The commencement will be on Wednesday of week after next."

He held the chair at Pittsfield for eight sessions. Among his colleagues were Childs, Dewey and Willard Parker, who was a very special friend. In a letter of October 2, 1836, he says: "Parker, with his sunny face and his hearty welcome, was in a few minutes after my arrival. It does one good to meet such men."

In 1839 he was appointed to the chair of practice in Dartmouth College, Hanover, N. H., the school founded by Nathan Smith in 1798. In a letter to his friend, Green, dated September 8th, he gives brief sketches of some of his colleagues, among them a delightful account of Oliver Wendell Holmes, then a young man of thirty. "Dr. Holmes you know something of. As a teacher there is no doubt of his success, although he will not show himself during this his first course. He has his anatomy — some of it at least — to study as he goes on, and he has not yet got the whole hang of the lecture-room — he does not give himself his whole swing. His attainments in medical science are extensive and accurate, and his intellectual endowments are extraordinary. His mind is quick as lightning and sharp as a razor. His conversational powers are absolutely wonderful. His most striking mental peculiarities consist in a power of comprehensive and philosophical generalization on all subjects, and in a fecundity of illustration that is inexhaustible. His talk at table is all spontaneous, unpremeditated, and he pours himself forth — words and thoughts — in a perfect torrent. His wit and hu-

mor are quite lost in the prodigal exuberance of his thoughts and language." In this same letter is the following characteristic memorandum, illustrating his desire to see the schoolhouses beautified and adorned. "One word about the High School House. Pray, don't forget in the planning of the rooms my plan for some embellishments. Even if we should get some busts I do not know that niches would be any better than suitable stands or shelves. I hope we shall raise, by a fair, from five hundred to one thousand dollars for pictures, etc., for ornaments to the two principal rooms." It is quite possible that Bartlett lectured both at Woodstock and at Pittsfield, as the terms were purposely arranged so as not to clash, and in the catalogue of the Vermont Medical College, 1844, there is an advertisement of the Berkshire school. The names of Bartlett and Holmes occur only in the 1839–40 and 1840–41 announcements.

In 1841 he accepted the chair of the theory and practice of medicine in the Transylvania University, Lexington, at that time the strongest and best-equipped school in the West.[4] On his way to Lexington he visited New York, Philadelphia, Washington and Baltimore, and in a letter to Green, of September 7, 1841, he gives an interesting account of the men he met in these cities. One item is of interest to Baltimoreans: "Day before yesterday I spent with Dr. Nathan R. Smith, at Baltimore, on my return from Washington. I found him very attentive and hospitable. He took me into his gig and went to see some of his patients. He has a pretty large surgical practice, and is, I should think, a man of excellent sound sense, industrious, and devoted to his profession — not so *great* a man as his father, but a very capital good fellow. He speaks well of Lexington and the school — says it is the best appointed school in the country."

In his letters there are interesting descriptions of his life in Lexington, some of which are worth quoting: "In the school we are getting on very well. The class is of a good size, rather larger than last year, worth a little over $2,000, intelligent, attentive, well behaved. I have given fifty-eight lectures, and we have just six weeks more. My own success has been good enough, I think. So far as I have means of judging, my instruction is entirely satisfactory, to say the least. My colleagues — Dudley, you know, is the great man here. He has many peculiarities. He is very much pleased with me. He teaches singular doctrines, and follows, in many things, a practice very peculiar to himself. The other day he tied the common carotid before the class in an anastomosing aneurism in the orbit; patient from St. Louis. Day before yesterday he cut for the stone; patient, a lad from Mississippi. He has two more cases of stone here for operation. He is exceedingly cautious; sends many patients, of all sorts, away without operation. Uses the bandage for everything almost in surgery — tart. ant. and starvation, or low diet, in most diseases. He had a pretty large property, 'a garden' as he calls it, of 150 acres or so, a mile from the city. Richardson, in obstetrics, boards with me, a plain, common-sense man, who fought a duel in early life with Dudley; has made a pretty large fortune here in practice, and now lives in the country eight miles or so from here, on a farm of 500 acres. The style of lecturing here is quite different from what it is in the East — more emphatic, more vehement. It is quite necessary to fall somewhat into the popular style. We stand, in the lecture-room, on an open platform with only a little movable desk or table, on which to lay our notes. On the whole I like it better than being seated in a desk, as they are in Boston." (December 21, 1841.)

In March, 1843, he writes to Green that his receipts for the session have been more than $2,000. "There are a few good families who send for me, and I get occasionally a consultation. We never make a charge less than a dollar; and consultation visits in ordinary cases — the first visit — are $5.00. These few enable me, situated as I am, to make even a small and easy business somewhat profitable. I have made one visit, twenty-five miles distant, for which the fee was $25; and I saw a second patient, at the same time, incidentally, for $5.00 more. You see from all this, that my place gives me rather more money than I could earn in Lowell, for a much smaller amount of responsibility and labor. I have hardly, indeed, been called out of bed during the winter. In a business point of view I feel quite content with my situation."

From an interesting account of a consultation in the country we can gather how the planters of those days did their own doctoring: "Col. Anderson belongs to a class of men, pretty large, I think, in this State, — rather rough, with a limited school education, but intelligent, shrewd, clear-headed, and enterprising. He has a farm, entirely away from any travelled road, of 500 acres; but his principal business is that of bagging and soap manufacturing, his farm serving only to feed his family. This consists of about one hundred, eighty or more of which are his negroes. He has no physician, whom he is willing to trust, nearer than Lexington; and in nearly all common acute diseases treats the patient himself. His daughter, Mrs. Breck, was seized with acute pleurisy, soon after miscarriage, and her father had bled her twice, pretty freely, and given calomel and antimony, before any physician had seen her. He had followed the same course a year ago in the case of his wife." (February 18, 1844.)

In the same letter he says: "Typhoid fever has been very widely prevalent in many parts of Kentucky for the past year. There were, it is said, 200 deaths in an adjacent county last summer and fall. It is evidently the common fever of this country, with all the features so familiar to us at the East."

In the autumn of 1844 he accepted the chair of the theory and practice of medicine at the University of Maryland. Among the letters I find but one from Baltimore, and that is to Oliver Wendell Holmes about a review of his book, "The Philosophy of Medical Science," which had appeared that year.

In 1844 he accepted the chair of materia medica and obstetrics in the Vermont Medical College, the session of which began in March and continued for thirteen weeks. Among his colleagues were Alonzo Clark, Palmer and Edward M. Moore and later John C. Dalton. Bartlett's name occurs in the catalogues of the school until 1854, the year before his death. In May, 1845, he and Mrs. Bartlett sailed for Europe. In a letter to Green, July 12th, there is an interesting reference to Louis and to James Jackson, Jr. "I have seen a good deal of Louis, who has been very civil and attentive. I dined with him soon after my arrival, and met there, amongst others, Leuset and Grisolle, two of his most intimate medical friends. I never see him

[4] History of the Medical Department of Transylvania University and its Faculty, by William J. Calvert, Johns Hopkins Hospital Bulletin, August, September, 1899.

that he does not speak of young Jackson — *ce pauvre Jackson*, as he calls him. He told me, with a great deal of feeling, that Jackson, the last night that he spent in Paris, wrote him a letter from his hotel, which was moistened with his tears, and that he thought Jackson was almost as much attached to him as to his father."

In another letter he speaks, too, of his very cordial reception by Louis. They spent the winter on the Continent, travelling about, chiefly in Italy, and in the spring went to London. In a letter dated June 17, 1846, there is an interesting sketch of a magnetic séance at the house of Professor Elliotson, of University College, who subsequently came to such a grief over hypnotism. "And then he ran full tilt off upon his hobby, 'animal magnetism,' calling it one of the most sacred and holy of all subjects, one of the greatest truths, and so on. Dr. Forbes, the editor, he spoke of as 'a wretch,' all because the doctor has shown up some of Elliotson's magnetic operations. Dr. E. afterwards invited me to see some magnetic phenomena at his house. I went about three o'clock in the afternoon, and found his spacious and elegant drawing-room quite filled with well-dressed gentlemen and ladies, assembled for the same purpose. The doctor had two subjects, one a young, delicate looking girl, and the other a damsel of a certain age, upon whom he performed the standard and stereotyped experiments — putting them into the magnetic sleep, stiffening their limbs, leading them round the room with a common magnet, exciting their phrenological organs, and so on. I can only say that I was not specially delighted with Elliotson's manner, and that if I was to choose a man by whom I should swear, without using my own eyes, certainly it would not be him."

In the same letter he speaks of having seen a great deal of Forbes, editor of the *Medico-Chirurgical Review;* of Marshall Hall, of Walshe, "a young man and a good fellow"; of Sir Henry Holland, and of that interesting American physician, who lived so long in England, Dr. Boott, and of Dr. Southwood Smith, at the Fever Hospital.

On his return from Europe we find him during the session of 1846–47 in his old chair at Lexington, whence he writes on March 18, 1847, to his friend Green, from which a paragraph relating to the second edition of his book on "Fevers" may be quoted: "I have been drudging away all winter at my second edition. I do not feel any great interest in it, though I hope and intend to make a good book of it. The first edition, for a monograph, has sold very well, mostly at the South and West; so well at least that Lea & Blanchard propose publishing the second edition and paying also something for the right to do so."

The next sessions of 1847–48–49 were also at the Transylvania University. In the spring of 1848 there is a letter from Pliny Earle, dated April 16th, saying that he had received a catalogue of the Medical Department of Transylvania University, from which he had received his first intimation of Bartlett's resignation of the professorship. He asks Bartlett's advice as to the propriety of applying for the position.

On March 13, 1849, he received the appointment as professor of the theory and practice of medicine in the University of Louisville. At this time, in a letter from Dr. J. Cobb, we have the first intimation in the letters of ill health, as there is the sentence: "Accept my best wishes for your complete restoration to health."

The University of Louisville had drawn heavily upon the classes of the other Western schools, chiefly at the expense of Lexington, and the Faculty when Bartlett joined it was very strong, comprising such well-known men as the elder Gross, the elder Yandell, Rogers, Benjamin Silliman, Jr., and Palmer.

The condition of medical politics at that time in the town of Louisville was not satisfactory, and a new school had been started in opposition to the University, and among the Bartlett letters are a number from the elder Yandell which show a state of very high tension. Bartlett spent but one session in Louisville. He and Gross accepted chairs in the University of New York. The appointment of the former to the chair of the institutes and practice of medicine is dated September 19, 1850. From some remarks in a letter from Yandell it is evident that Bartlett did not find the position in New York very congenial. Gross found his still less so, and returned to Louisville the following year. J. W. Draper, the strong man of the University School, had secured Bartlett and in a letter dated August 12, 1850, he promised him a salary of at least $3,500. The same letter shows how thoroughly private were the medical schools of that day: "It perhaps may be proper to repeat what is the condition of the real estate. The college building is owned equally by the six professors. Its estimated value when Dr. Dickson left us in the spring was $78,600, and there is a mortgage upon it of $48,000, bearing interest at six per cent. Excluding this mortgage the share of each professor is therefore $5,000, and a mutual covenant exists among us that on the retirement or decease of one of the Faculty his investment shall be restored to him or his heirs — the new-comer starting in all respects in the position he occupied."

During these years Bartlett seems to have been very busy at work at the microscope, and there is a letter from Alonzo Clark, dated June 15, 1848, descriptive of a fine new Oberhauser (the Zeiss of that day), and in 1851 there is an interesting letter from Jeffries Wyman, giving a list of the most important works on invertebrate zoölogy.

Among his colleagues in the University were Draper, Martyn, Paine and Patterson. Things do not seem to have worked very smoothly. In the spring of 1851 overtures were made to him from the College of Physicians and Surgeons of New York, in which Faculty were his warm friends, Alonzo Clark and Willard Parker, and he was elected to the chair of materia medica and medical jurisprudence in the following year, in 1852. Here he lectured during the next two sessions until compelled by ill health to retire.

I may fittingly conclude this section of my address with a sentence from a sketch of his life by his friend Elisha Huntington: "Never was the professor's chair more gracefully filled than by Dr Bartlett. His urbane and courteous manners, his native and simple eloquence, his remarkable power of illustration, the singular beauty and sweetness of his style, all combined to render him one of the most popular and attractive of lecturers. The driest and most barren subject, under his touch, became instinct with life and interest, and the path, in which the traveller looked to meet with briers and weeds only, he was surprised and delighted to find strewn with flowers, beautiful and fragrant. There was a magic about the man you could not withstand; a fascination you could not resist."

(To be continued.)

THE VALUE OF X-RAY EXAMINATIONS IN THE LESS FREQUENT DISEASES OF THE CHEST ILLUSTRATED BY THEIR USE IN THOSE CASES WHERE ANEURISM IS PRESENT OR SUSPECTED.

BY FRANCIS H. WILLIAMS, M.D., BOSTON.

IT is now recognized that x-ray examinations are of special value in diseases of the organs within the chest. In the hands of those trained in their use they point out very early departures from the normal in pulmonary tuberculosis; assist in the early diagnosis of other diseases of the lungs and pleuræ, and enable the physician to determine the size of the heart and displacements of that organ more accurately than has hitherto been done. They are also valuable in the less frequent diseases that have their site in the chest, behind the sternum, and I will illustrate their aid in this direction by presenting several cases of aneurism. The diagnosis of these cases is often difficult and sometimes impossible by the ordinary methods. Aneurisms are not infrequently overlooked in their early stages, the time when there is the best opportunity for prolonging life; or, if recognized, their extent is not appreciated; or their presence is suspected when they do not exist. Therefore, in order to get as accurate a knowledge as possible of the condition of the thoracic cavity, the chest should be examined by means of the fluorescent screen, both in front and behind. An x-ray photograph may also be taken, and should be taken if there is a question of a new growth. This x-ray examination of the chest may show, for example, that the outlines seen on the fluorescent screen, on one or both sides of the sternum, differ from those that present themselves in health. Whether or not this variation from the normal is due to a new growth or to an aneurism cannot always, of course, be determined by the x-rays alone. They furnish only one way, though a very valuable way, of studying this region.

But if any departure from the normal outlines in this portion of the thorax is found, the physician should determine whether or not there is pulsation and whether the abnormal outline is nearer the front or the back of the chest. This latter fact can be ascertained by making two examinations of the patient; that is, first with the fluorescent screen placed on his chest, and second, on his back. To accomplish this end the patient may be turned, or the Crookes tube may be moved. The spinal column should be examined to see if there is any displacement of the vertebræ which might push the aorta to one side; for if through disease in the vertebræ or some neighboring part the descending aorta is pushed a little to the left, this condition might be confounded with an aneurism, if the knowledge of this possibility were not in mind and this region carefully examined. If there is disease of the spine, producing displacement of the aorta, a careful x-ray examination of the line of the vertebræ would reveal the cause of its unusual position.

Moreover, in some healthy individuals the aorta is more prominent than in others. I have examined some persons in whom there was no trace of aneurismal dilatation, but in whom the outline and even the pulsation of the descending aorta could be followed.

Further, care must be taken to distinguish between new growths in the thorax and an aneuri-m. For this purpose a careful determination of the position of the outlines, not only laterally but anteroposteriorly, is important. If, for example, when examining the chest, a small shadow is seen on the fluorescent screen in the neighborhood of the descending aorta on the left of the sternum, the physician must determine whether it is cast by something situated in the front or back of the chest. For if a small shadow on the left of the sternum is produced by something in the front of the chest, the diagnosis of aneurism may be excluded. The position of the object producing the shadow as regards its relation to the back and front of the chest of the patient may be readily determined by a method I devised for locating foreign bodies.[1] As a rule, an aneurism of the ascending portion of the aorta will be found nearer the front of the chest than the back; whereas aneurisms of the descending aorta in the early stages would be found nearer the posterior portion of the chest than the anterior. If pulsation of the outline is seen, we probably have to do with an aneurism, though it is possible that a movement might be given to a new growth situated over the aorta.

Let me diverge a moment here from the immediate subject to say that new growths in the chest may be often recognized better by x-ray examination in the early than the later stages, because when the disease has progressed so far as to fill up the thoracic cavity it is difficult to know whether the appearances seen on the screen are due to the presence of a new growth or to some conditions which make the lungs and pleuræ denser than normal. Furthermore, if a new growth is present and if surgical interference is necessary, it is of the first importance that a diagnosis be made at the earliest moment.

In aneurisms of much size the heart is often displaced or greatly enlarged. In making a diagnosis of a given case, the outline of the shadow seen on the screen should be carefully drawn upon the skin with a suitable pencil, both on the front and back of the chest, and, as already stated, the physician should determine whether the object causing the shadow is nearer the front than the back of the chest. The history of the case should also be carefully considered, the patient's age and the duration of the symptoms; for while in some cases the diagnosis of an aneurism is a very simple matter with the aid of the x-rays, it may in others be difficult to recognize the cause of the abnormal outline found by means of the fluoroscope.

In general, it may be said that aneurisms of the thoracic aorta may be seen by the x-rays before there are physical signs; that where it is desirable to be sure that no thoracic aneurism exists the x-ray examination can render much service. There are cases which produce troublesome symptoms, such as dyspnea, pain in the chest, and dulness to percussion over an area which might easily be the site of an aneurism; these symptoms may give the physician much anxiety if he is led to consider that they are due to this cause. In these cases it is a satisfaction to the patient and to the physican to be able to exclude the presence of an aortic aneurism, and while by means of an x-ray examination we cannot always be sure that the appearances seen are caused by an aneurism, we may be quite sure that no aneurism is present if the x-rays give

[1] See Medical and Surgical Reports, Boston City Hospital, January, 1897.

normal outlines in the thoracic cavity when careful examination of the patient in various positions has been made. Herein lies one of the advantages of this method of examination. It may give us greater assurance of the absence of an aneurism of the aorta in suspected cases than any other evidence that we can have. Other causes may produce outlines on the fluorescent screen which simulate those given by aneurisms, but the history, want of pulsation, position, etc., will assist us to recognize the true cause of the appearances.

Cases of aneurism may give physical signs suggestive of tuberculosis, neuralgia, or esophageal stricture. The cases given below illustrate some of these points.

I have examined with the x-ray 34 cases where aneurism was suspected, and one case to determine the size of the heart, when an unsuspected aneurism was discovered; 35 cases in all. Of these cases, 15 had typical aneurisms; six had more or less dilatation of some portion of the aortic arch; one showed an outline suggestive of aneurism of the aortic arch, but there was no pulsation. This abnormal appearance was proved by an autopsy to be due to a mass of glands. The remainder gave normal outlines in the region where an aneurism had been suspected.

The number of cases, 15, is not sufficient to justify an elaborate analysis, but some detail and the accompanying charts will, I think, be of interest. In 13 of the 15 cases the aortic arch was the seat of the aneurism; in one of these there was a second aneurism in the innominate artery also; in the fourteenth case there were two aneurisms, one in the innominate and another in the subclavian artery; in the fifteenth case the aneurism was in the subclavian artery. Eleven of these cases were males and four females; 11 were between thirty-eight and forty-five years of age; two were thirty-three; one was forty-nine and one fifty-nine and one twenty-nine. A syphilitic history was obtained in four cases. Pain was present in 12 cases, and alteration of voice in 11. Laryngoscopical examination was made in seven of these last cases, which showed paralysis of the vocal cord. The physical examination of 12 out of 14 of the cases of aortic aneurism was given in the hospital records; in five cases there were no physical signs of aneurism; in eight cases the heart was enlarged, and in five of these there were murmurs indicative of valvular defects, four of which were aortic and one mitral. Arteriosclerosis was found in the three cases in which an autopsy was made. No nephritis was found in any case.

I desire to thank Dr. M. P. Smithwick for assisting me in getting together the notes of these cases.

ANEURISM SUGGESTING PULMONARY TUBERCULOSIS.

CASE I.[1] M. J., a man aged fifty-nine years, referred to me October, 1896, by Dr. M. P. Smithwick, illustrates the increased accuracy in diagnosis that an x-ray examination may afford. The great size of the sac seen on the fluorescent screen suggested early rupture, and therefore a frank statement of the case was made to the patient and gratefully received by him, as he was thus given an opportunity for a much-needed arrangement of business affairs.

Family history.— Father died of consumption at seventy-two years of age. It was usual for the males of the paternal branch of the family to develop that disease after fifty-nine years. Mother died of apoplexy. The patient, his family, and his physician did not doubt that he was following the family tradition and developing tuberculosis. It was not at all surprising that the mistake should be made when we compare the clinical picture of hemoptysis and cough with the physical examination, which gave râles at the left apex. The husky voice led one to suspect laryngeal tuberculosis.

Previous history.— Always "short-winded." About four years ago he suddenly became unconscious for about a minute. There was no warning, and recovery was immediate. About June 15, 1896, he began to be hoarse and grew rapidly worse, and had some cough. About this time, while running after some colts, he had marked dyspnea. This symptom has increased, although he can walk a distance if careful. On July 15th he first raised a little blood, rather dark in color, and this has occurred from time to time since, especially after talking. Four or five times since October 1st he has had short and sharp attacks of pain that start in the "pit of the stomach" and radiate to

FIG. 1. Case I.

left shoulder and down left arm to elbow. There is numbness of the left arm associated with this pain.

Physical examination.— The voice is shrill and husky. Examination of the larynx by Dr. Leland shows the left cord paralyzed and fixed in median line. The arteries are quite resistant and nodular, and somewhat tortuous. The heart area is decidedly diminished, action is regular and fairly strong. Apex beat in sixth interspace apparently outside of the nipple. The aortic first sound is rough; second sound is ringing and valvular. Lungs: resonance somewhat exaggerated. Over upper left chest, resonance, respiratory murmur, vocal fremitus and voice sounds somewhat exaggerated, especially in front. At left apex and to second rib in front are numerous fine moist râles. A faint pulsation is to be felt by pressing the chest between the two hands. It seems most marked at the junction of the second rib with the sternum.

X-ray examination made October, 1896, showed that the patient had a large thoracic aneurism, as indicated in Fig. 1.[2] Some weeks later, after returning from a drive, death occurred suddenly. There

[1] This case was published by me in the Medical and Surgical Reports of the Boston City Hospital, 1897.

[2] The cuts are reproductions of the tracings made by means of the fluorescent screen; I have not attempted to give reproductions of x-ray photographs as these reproductions are so often unsatisfactory.

was profuse arterial hemorrhage from the mouth. Failure to observe necessary precautions may have hastened the end.

ANEURISM OF AORTA, WITH PERFORATION INTO ESOPHAGUS; AUTOPSY.

Such cases remind us that aneurism should be excluded before we dilate a supposed esophageal stricture.

CASE II. E. H. was admitted to the service of Dr. George G. Sears at the Boston City Hospital, June 13, 1898, and was referred to me for x-ray examination June 17th. The following history was given: Family history was negative. Past history: neither syphilis nor rheumatism; alcohol in moderation.

Present illness.— Slight pain began in cardiac region five months ago; a month later it was felt in front of right chest; and two weeks later just to right of spinal column at level of lower angle of scapula; it was a dull ache and has persisted and increased in these three places; cough increases the pain but full

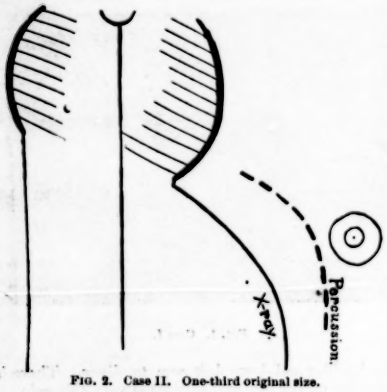

FIG. 2. Case II. One-third original size.

inspiration does not; on swallowing, pain begins at level of thyroid and extends along the spine to lower dorsal region; solids are regurgitated occasionally; meat causes severe pain unless finely minced; no cough nor palpitation; dyspnea and hoarseness three weeks.

Physical examination.— Left vocal cord partially paralyzed; pulmonary resonance good, being slightly exaggerated over right front; respiration harsh and wheezy; on full inspiration sounds much prolonged on right side; cardiac area extends from mid-sternum to nipple line; sounds normal; apex in fifth interspace; pulsations seen over greater part of sternum; radial pulse regular, good strength and volume; no edema of extremities; urine normal. Diagnosis of aneurism of aorta.

X-ray examination.— Figure 2 gives the outline of the aneurism seen on the fluorescent screen, as well as the left border of the heart, which border was much nearer the median line than Dr. Sears and I had placed it by percussion.

To go back, three weeks after admission patient raised a pint of dark blood. Two days later felt unable to swallow solids or liquids, and after two more days the stools were tarry. Died. A post-mortem examination was made by Dr. Mallory, and I quote a part of the record. "Intestines contain dark material. In posterior wall of transverse arch of aorta, three millimetres below beginning of left subclavian artery, is an opening 12 x 18 millimetres. This opening is directly connected with a reddish-gray clot projecting through anterior wall of esophagus by an opening 4 x 5 centimetres with thin, retracted, dark greenish edges. Lower border of esophageal perforation is on level with bifurcation of trachea. Intima of aorta everywhere thickened. Many elevated yellowish placques. No areas of softening nor calcification. Weight of heart 270 grammes. Valves and cavities normal. Some fatty degeneration of muscle microscopically. Lungs very edematous.

"*Anatomical diagnosis.*— General arteriosclerosis. Aneurism of aorta with perforation into esophagus."

SUBCLAVIAN ANEURISM; X-RAY EXAMINATION BEFORE OPERATION TO EXLUDE EXTENSION BELOW CLAVICLE.

Before ligating the subclavian, carotid, or innominate arteries for aneurism, it is manifestly desirable to know the extent of the aneurism, and whether or not there is also an aneurism of the aorta. In the following case the innominate artery was ligated by Dr. George W. Gay, and the case was reported in the *Boston Medical and Surgical Journal*, July 22, 1897.

CASE III. A. McC., widow, thirty-nine years of age, was admitted to my service at the Boston City Hospital, February, 1895.

Family history.— Mother died of pulmonary tuberculosis.

Past history.— No history of syphilis or rheumatism. Some months ago raised blood several times during two days. Five days before admission commenced to be restless and nervous, with palpitation and dyspnea. Weak and dizzy until the afternoon of the fifth day, when she raised blood for some hours before and after being brought to the hospital. Neither in this attack nor previously had there been nausea or cough. On exertion her "heart beat in her throat." Three times during that month she raised a small amount of blood, apparently when excited.

Physical examination.— Radial arteries not resistant, their pulsations equal, regular, poor volume and strength. Cardiac area normal; apex beat in fourth interspace, just inside mammary line; action regular and fairly strong; at apex a very low-pitched systolic murmur not transmitted toward axilla; similar murmurs heard over the base. Along both sides of vertebral column from occiput to last dorsal vertebra is a rather low-pitched systolic murmur, most distinct at first dorsal vertebra and diminishing in intensity up and down. In supraclavicular notch and above right clavicle is an unusually marked pulsation. Pulmonary resonance and respiration good. Abdomen negative except for a very movable right kidney.

From this time until October, 1896, when patient was admitted to Dr. Gay's service for operation, she returned to the hospital at intervals, for examination by Dr. Smithwick. Soon dysphagia commenced; dyspnea was accompanied by some paroxysms of coughing, and the throbbing in the neck was attended by dull pain extending to the right axilla and back. Exertion and excitement increased these symptoms.

Hoarseness developed. During the six months before operation the symptoms were all worse, and her condition wretched. With the exception that the pulsation was more marked, the physical examination had not changed since February, 1895. Aneurism was suspected then, but was now certainly present.

To determine the lower boundary of the aneurism, and to ascertain if the aortic arch were involved, Dr. Gay referred the case to me for x-ray examination, with diagnosis of fusiform aneurism of the innominate, subclavian and carotid arteries. *The x-ray examination* showed the outline of the portion of the aneurism above the clavicle, and demonstrated that there was no extension of the aneurism below the clavicle and that the lungs were normal. The x-ray examination was confirmed by the autopsy.

DIAGNOSIS OF ANEURISM CONFIRMED BY X-RAY EXAMINATION.

CASE IV. C. S., a house painter, thirty-six years old, had a well-defined aneurism of the aorta, but no history of dyspnea.

History. — Syphilis eighteen years ago; well until

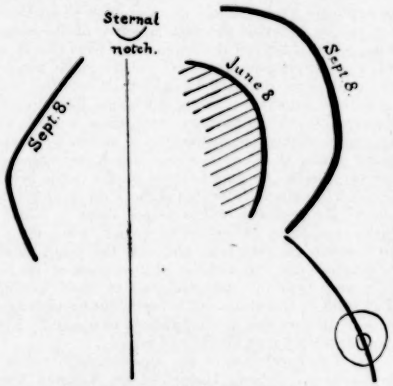

FIG. 3. Case V. One-third original size.

eight months ago, when dull pain with occasional paroxysms of sharp pain began in front of chest, in left arm to the elbow, and later shot up left side of back of neck and head. The pain has been constant from the beginning, and nine weeks ago became so excruciating that he was compelled to cease working. No weakness or tenderness of the arm; hoarse five or six weeks; no dyspnea; constipated; appetite poor.

Physical examination. — Well developed and nourished; voice high-pitched; pupils equal and reactions normal; no paralysis of ocular muscles; neither wrist nor toe drop; grasp normal; lead line present. Tracheal tug; radial pulses alike; cardiac area and sounds normal except in second interspace to left of sternum, where first sound is prolonged and second sound slightly accentuated; at apex of left lung in front, to third rib, and behind to spine of scapula, vocal resonance and fremitus are diminished; no rales; on full inspiration right side of the chest is the more expansive. Laryngoscopic examination by Dr. Leland showed right vocal cord normal, left paralzyed.

X-ray examination showed a well-defined dark area in upper left chest, extending out from the aorta and expanding with every heart-beat. The excursion of the diaphragm on the left side was much diminished as compared with the right.

ANEURISM SUGGESTING INTERCOSTAL NEURALGIA; SUSPECTED ANEURISM CONFIRMED BY X-RAY EXAMINATION. THESE EXAMINATIONS ENABLE US TO DETERMINE WHETHER AN ANEURISM IS OR IS NOT INCREASING.

CASE V. E. M., thirty-three years of age, referred to me by Dr. J. J. Putnam, for x-ray examination with reference to aneurism. Patient had suffered with what appeared to be severe intercostal neuralgia. The pain was in his left arm, left side, and below the ribs. It had been severe for two months, sometimes by day, but especially at night. There was a specific history.

X-ray examination made June 8, 1897, showed a small aneurism of the descending portion of the aortic arch, which is indicated in the diagram (Fig. 3) by the shaded lines of the inner outline marked June 8th. A second x-ray examination made September 8, 1897, gave the outline marked in the diagram September 8th, which demonstrated that the aneurism was increasing. Later the physical signs of aneurism became well marked, the pulsation being easily palpable.

(To be continued.)

REMARKS UPON THE GUNSHOT WOUNDS OF THE REDUCED-CALIBRE RIFLES IN THE SANTIAGO CAMPAIGN.[1]

BY MAJOR LOUIS A. LA GARDE,
Surgeon, United States Army, Commanding Base Hospital, Fifth Army Corps, Siboney, Cuba.

OUR knowledge of the rifles of reduced calibre propelling armored projectiles dates from the publication of Professor Hebler's pamphlet in 1882. In his original monograph Hebler claimed certain advantages for the reduced-calibre rifle and among these were the following: (1) Lighter ammunition; (2) flatter trajectory and greater dangerous space; (3) less deviation by wind; (4) less recoil; (5) greater penetration; (6) greater accuracy; (7) the wound produced, while being sufficient to disable, is much more humane.

Some of these advantages were so apparent that they could not be refuted, while the others required the proof by experiments, or the test by actual conditions in the field.

That the ammunition is lighter there is no doubt, since a soldier who carries 100 rounds of the older ammunition can carry for the same weight about 180 of the new ammunition. That the trajectory of the new rifle is flatter, and that the dangerous space is consequently greater, is also apparent, since those versed in ballistics have shown us that the point-blank range of the older gun of the Springfield pattern is 300 yards whilst that of the Krag-Jorgensen rifle, our present service gun, is 570 yards about.

The advantage of less recoil is perfectly apparent to any one who will shoot the two last-named weapons one after the other. The remaining advantages claimed by Hebler were not so readily determined. Greater

[1] Read before the Association of Military Surgeons, September 28, 1899, at Kansas City, Mo.

accuracy and less deviation by wind had to be determined by comparison at target. Although the small-bore guns and ammunition have been perfected very much of late it is yet a fact that, in the remote ranges, the smaller and lighter projectile is more influenced by wind than the heavier and larger leaden bullet and that for these ranges it is not so accurate.

Greater penetration was another important advantage claimed by Hebler which was sustained by experiment. In unseasoned oak, firing across the grain three feet from the muzzle, the old leaden 45-calibre bullet from the Springfield rifle penetrates but 5–6 inches, whilst the steel-jacketed bullet of our present service rifle at the same distance will penetrate 19–20 inches.

The last of the advantages claimed by Hebler and the one of greatest interest to mankind was that *the wound produced, though sufficient to disable, is much more humane.* This claim could only be determined by experiments on cadavers, lower animals, and the actual conditions in battle. Experimenters set to work in all the countries from 1886 to the present time to ascertain the character of the wounds, first, on lower animals, second, on dead human bodies. The Surgeon-General of the Austrian Army, Johann Habart, Chauvel and Nimier, of the French Army, Bruns, of Germany, and many others have furnished us important data upon the effects of the new arm. In this country it was my good fortune to be able to test the rifle for the War Department in 1893.

Although there was some difference in the mechanism of the guns used by the different experimenters the projectiles which they propelled differed but little as to calibre and destructive effects. The most of the experiments were conducted at simulated ranges, whilst some few were conducted at the actual ranges. That is to say, taking our work at Frankford Arsenal as example, all of the firing was done at 53 feet. When we desired to obtain the effects of a bullet at a certain range, the charge of powder was reduced in quantity enough to give to the bullet the remaining velocity for that range. The results thus obtained were generally unanimous, and, as far as the experimenters were concerned, sufficiently conclusive.

On the other hand, there were many writers who doubted the propriety of adopting these results as similar to those which must eventually obtain on the living subject at actual ranges in battle. Inasmuch as we are now in possession of the accumulated experience of a few wars it would seem pertinent at this time to study the results of the experimenters and the conditions seen in battle side by side.

I will now review in detail the conclusions summed up at the end of our experimental work at Frankford Arsenal and compare them with what I observed in the Santiago campaign:

(1) The experimental evidence showed "the shock impressed upon a member increases with the velocity whether a bone is traversed or not. It is always greater with the leaden projectile." This diminution in shock has been one of the serious objections advanced against the adoption of the small bullet by military men. They feared that one wound would not suffice to throw a man *hors du combat*, and that he might be able to go on fighting regardless of the fact that he had been hit a number of times. Whether this is true of savage tribes, or horses in a cavalry charge, it is not true of our American soldiers. Upon inquiry among line officers in the Santiago campaign I find that as a rule to which there were very few exceptions men when hit fell back to the rear at once; and I can testify to the fact that scores of them walked back to the hospital at Siboney with wounds that were most trifling in their nature.

(2) "The explosive effects at very short range are about the same for the two projectiles. They continue however up to 350 yards with the smaller bullet and cease at about 200 yards with the leaden bullet." I only saw one case which approached anything like explosive effects in Cuba. That was the case of a captain of the Rough Riders shot in the lower third of the tibia. The wound of entrance was about the calibre of the Mauser bullet that had inflicted it, and the wound of exit was irregularly round, a half-inch in diameter. There were two smaller wounds near the wound of exit, which were undoubtedly made by spiculæ of bone which had been driven forth acting as secondary missiles. The area of fracture was about four inches above the ankle; it was marked by a cavity in which many loose fragments of bone lay, none of them measuring more than a half-inch. The wall of the cavity showed bony sand driven into the soft parts. The infrequency of explosive effects should in my opinion be attributed, (*a*) to the fact that the vast majority of the wounds were inflicted beyond the zone of explosive effects, and (*b*) since explosive effects are chiefly to be noted in the vital parts contained in rigid walls, like the brain, or in those organs containing much fluid, like the heart, liver, spleen, the alimentary tract, these wounds with explosive effects, so destructive to tissue, were numbered among the dead — a class which, unfortunately, the surgeon has no time to study on the battle field.

(3) The experimenters found that "the smaller frontage of the jacketed bullets causes them to inflict injuries resembling subcutaneous wounds when the soft parts alone are traversed, and that the small wounds of entrance and exit and the narrow track of the missiles were favorable circumstances to rapid healing." The truth of this statement is borne out by the experience of all surgeons in the Santiago campaign. Flesh wounds healed very kindly and rapidly.

(4) This conclusion of the experimenters refers to hemorrhage. Johann Habart, of the Austrian Army, who paid special attention to this subject, states "that the blood-vessels are seldom torn by the small jacketed bullet, and that when wounded they are not closed so easily by coagulation as those severed by leaden projectiles."

Some writers have deduced from this statement that alarming or fatal hemorrhage would be more frequent in future battles. The experiences of the surgeons with the line before Santiago do not confirm these apprehensions. Of the 1,400 wounded, as far as I can learn, not one died of external hemorrhage. The brachial and femoral were tied a few times in the base hospital for diffuse aneurism. One case of wound of the subclavian was operated upon in New York and died after the operation. There were five cases of gangrene from injury to blood-vessels which required amputation.

(5) "Injuries inflicted outside the zone of explosive effects upon the shafts of the long bones always show less comminution with the small bullet of hard exterior. The fissures are often subperiosteal and the fragments are larger." This was true of the Mauser bullet wounds in Cuba. It was seldom necessary to

open up the wounds for the purpose of taking out loose fragments of bone. In a number of instances there was distinct guttering of the compact substance of long bones without fracture. The mobility in some instances was so slight that it was difficult to make out a complete fracture when from the location of the wounds it was certain that the bone had been traversed.

(6) "Beyond the zone of explosive effects the projectiles of hard exterior almost invariably perforate or gutter the joint ends of bones, and the lesions of the articulations are never so grave." This conclusion tallies exactly with what we saw in Cuba. I do not recall a formal excision of a joint for the mechanical effects of the Mauser bullet. Joints were opened to turn out blood clots, and in one instance of the knee I particularly remember, to locate a lodged ball, but never for the purpose of performing an excision. There were at least 20 cases of gunshot injury of the knee-joint alone. These were immobilized and shipped North; and as far as I have been able to ascertain they have done well. These results are a great contrast to those inflicted by the larger leaden bullet, which by its highly destructive effects must have caused a number of resections and amputations.

(7) "The projectiles of hard exterior lodge less frequently in the tissues than the old leaden bullet." The experience at Santiago among the wounded of both sides has shown a surprisingly large number of lodged balls. Although I am not prepared to state that the small-calibre bullet lodges as often as the old discarded leaden bullet, the frequency with which it did lodge was remarked upon by military surgeons generally. Dr. W. E. Parker, of New Orleans, an acting assistant surgeon in the base hospital, visited the Spanish hospitals in Santiago after the surrender, and in conversation with the Spanish surgeons he learned that our Krag-Jorgensen bullet had not lodged in their wounded as often as their Mauser bullet had lodged in our men. The explanation for this would seem simple enough. It should be remembered that we were on the aggressive in a region that was practically unknown to our troops, whilst the Spaniards were perfectly familiar with every foot of ground over which we must make the advance. As trained soldiers their officers had carefully studied the range at every point. With this valuable information in their favor they were in a position to commence an effective fire at remote ranges, say at 2,000 yards and more. We could not locate them as soon as they located us, and when we did locate them we had to study the range before we could commence an effective fire. It was while we were locating them and studying the range and gradually advancing that they placed so many balls into our soldiers. When we did commence an effective fire we had reached a point where the remaining velocity of our bullet on impact was sufficient to carry it through the body. There is another explanation which may be gathered from the difference in the energy of the two bullets at remote ranges. Our bullet being larger and heavier than the Mauser has greater energy at 2,000 yards and it will penetrate farther in the remote ranges than theirs. Again, ricochet shots, from the thick underbrush and broken ground, undoubtedly favored a certain percentage of lodgment. Many of the officers attributed the lodgment of projectiles to the use of defective ammunition used by the enemy. This point was so susceptible of proof that I instituted experiments to show the relative penetration of the Mauser and Krag-Jorgensen rifles. The tests were made in large blocks of well-seasoned yel'ow pine fired into, across the grain, three feet from the muzzle. The penetration of the Krag-Jorgensen ammunition was 24 inches plus, whilst that of the Mauser ammunition exceeded ours by nearly 10 inches, a demonstration which at once set at rest the idea of lodgment from the defective ammunition of the enemy.

(8) "The old leaden bullet more often leaves fragments of lead in the foyer of fracture." This is so true that it needs no contradiction. The leaden bullet was so soft that it often separated into a number of fragments upon striking resistant bone, whilst the steel-jacketed bullet seldom encounters resistance enough in the human body to disintegrate it.

(9) "As the projectiles of smaller calibre are less apt to lodge or to carry foreign substances into the wounds we will expect to find fewer cases of suffering due to the remote effects of unextracted foreign bodies." This is true of the smaller bullet, as shown in Cuba. There were but few instances where clothing or part of the equipment was carried into the wound.

(10) "The frontage of the jacketed bullet being much less and the fact that it does not lodge as often as the larger leaden bullet will contribute to increase the percentage of recoveries in gunshot wounds of the lungs." That was especially true of the wounded in Cuba. As a rule the wounds of the lungs were apparently so trivial that it was difficult to restrain the men in a recumbent posture.

(11) "Owing to diminished frontage the new bullet will cause less disfigurements in wounds of the face." That is especially true of three officers who received painful wounds of the face. Two of them had never been accused of being possessed of good looks, and strange to say, since their mishap they are much better looking than they were before. On cosmetic grounds the new bullet has some recommendations.

(12) "The projectiles of hard exterior are more humane than the old, resections and amputations will not be so often required hereafter, soldiers will be more often restored to the State useful members of the community instead of cripples and pensioners, and in point of economy, the new projectile confers a great advantage." This last conclusion is also in accordance with the experience in Cuba. There were but three primary amputations and not one of them was done for injury by the small bullet. They were all the result of shell injuries. From the foregoing I believe we should conclude that the work of the experimenters agrees with the conditions found in war, and that their work was not done in vain.

OTITIS MEDIA IN ALL GRAVE DISEASES OF INFANCY.[1]

BY E. H. POMEROY, M.D.,
Chief of Staff, Calumet and Hecla Mining Co.'s Medical and Surgical Service, Calumet, Mich.

I HAVE been forcibly impressed with the statement so frequently made in journals and addresses of late that pediatrics is the specialty of the general practitioner. Probably the overwhelming majority of calls to attend to children will be on account of gastro-

[1] Read at the fifth annual meeting of the Upper Peninsula Medical Society, held at Calumet, Mich., July 6, 1899.

enteric disturbances; but only secondarily at this time is it my intention to bring gastro-enteritis to the attention of this meeting. My idea is that most of the diseases of infancy are more positively, more comprehensibly, more demonstrably infectious from definite bacterial infection than we can easily prove in adults, or if toxemia from bacterial growth, also more definite; and that the pharyngeal postnasal chamber is the more easily comprehensible distributing point for infection to the middle ear, the brain, the lung, the stomach, the intestines; and the middle ear an incubator and generator promoting general toxic disturbance in very many cases of localized infectious diseases.

There have been a great many contributions to the subject of otology in young children during the past two or three years especially. Probably the one writer whose contributions have attracted the greatest attention and discussion is Ponfick, of Breslau. His principal article on this subject is entitled "The General Pathological Significance of Middle-Ear Diseases in Infancy." It was an address delivered at the Silesian Congress for Natural Culture in June, 1897, and published in the *Berliner klinische Wochenschrift* during the months of September and October following. Ponfick's attention to the subject was drawn by his personal observation of his own children, who had been dangerously ill with gastro-enteritis. The symptoms became alarming in spite of the most careful attention of himself and colleagues and increasingly so until the sudden amelioration, which was simultaneous with a discharge from the ear. The improvement in the gastro-enteric condition continued until there was a cessation of the discharge from the ear, then came a relapse of the gastro-enteric symptoms, very gradual and apparently in connection with some change or faulty preparation of the food. The change for the worse was so gradual and so naturally ascribed to the faulty food that the discharge from the ear was well-nigh forgotten, until it recurred and with it again a pronounced and sudden amelioration of the gastro-enteric symptoms. This happened not only with one child but with two or three in the same family. It impressed Ponfick so much that he, with his associates, observed carefully the condition of the ear in the first subsequent 100 autopsies of children under three years of age. The results of these post-mortems are embodied in what will now be designated Ponfick's table, which contains some most astonishing presentations of facts concerning not only gastro-enteritis but many other conditions in infantile mortality.

These 100 autopsies he has divided under two heads: Non-infectious diseases, and those from infectious processes, and subdividing these into groups according to the disease. In most of these cases the actual condition, or rather the condition of the middle ear, preceding death was not suspected, and the cause of death is given by the attending physician who had charge of the case at the time of the child's death. In only a few of these cases is the history of the case during life obtained. Among the non-infectious group is found a heterogeneous collection, two of congenital heart disease, one of extensive burns, and three of non-infectious dermatitis. Of these only one was found free of otitis. This was a five-and-one-half-months-old infant with a congenital heart disease. Although this would appear to have the least possible connection with otitis, yet the only other case of congenital heart disease in this group was a one-year-old child showing otitis media in both ears and both drums filled with pus.

In Rotch's "Pediatrics" we read that von Tröltsch found on examining 47 petrous bones taken from unselected children that the middle ear was normal in only 18. The other 29 ears showed in varying degrees purulent and sometimes mucous catarrh. Of 15 children with exudation in the middle ear, the youngest was three days and the oldest one year old; five were in their first month, two each in their second and fourth, and the others in their third, seventh, eighth and twelfth month. In every five examinations of the ears of new-born children Schwartze found the tympanum filled with pus in two. Wreden found in 80 ears of children a normal middle ear in only 14. I refer to this here as showing the necessity of examining the ear in all cases of grave disease in very young infants and not confining our attention to an examination in the exanthemata. Referring again to Ponfick's table, we find that the other three dying from non-infectious or traumatic skin disease, and during life wholly without suspicion of otitis, were found to be all cases of otitis and, with one exception, bilateral.

The second group or category, those of infectious processes, embraces 94 per cent. of all the cases collected; and this list is subdivided into (*a*) acute and (*b*) chronic; sub-group (*a*) including all excepting the 16 cases of chronic tuberculosis and the three of congenital syphilis.

In Sub-group 1, of infectious dermatitis, such as erysipelas and furunculosis, there was not one free of otitis, and three of the four were otitis media purulenta bilateralis. In this connection Dr. Edward H. Clarke's statement, which has been largely quoted by other writers on otology, must be referred to. His statement is that the physician who neglects the examination of the ear in the course of the exanthemata of

children should be denominated an unscrupulous practitioner.

In Group 2 of our table are six cases of diphtheria with three absolutely free of otitis. This must be considered either accidental or very astonishing, as diphtheria has been and naturally would be held from its nature and the localization of its symptoms as directly conducive to otitis. To me, however, this showing is comprehensible when we remember the acuteness with which diphtheria manifests its localized symptoms in the throat. I mean by this that the local inflammation is so early and so intense near the pharyngeal end of the Eustachian tube that the Eustachian orifice is closed in many cases before the germs gain entrance into the tympanic cavity.

In Group 3 the one case of scarlatina gave otitis media on both sides. In Group 4, among the 11 cases of uncomplicated pneumonia there was only one, a six-months-old child, in which otitis was absent. In the other 10 cases, ranging in age from two to fifteen months, all showed otitis and in every case purulent and bilateral.

Groups 6 and 7: In these groups there was the greatest difficulty of classification, on account of the tendency to designate differently among different physicians the cause of death in cases where there is a complication of pulmonic and enteric disease. In these two groups as designated, however, we find the great proportion of 35 per cent. of all cases tabulated in this paper. All cases of gastro-enteritis are designated as acute up to the fourteenth day; all in which the duration is beyond that time, as chronic. In the eight cases of acute gastro-enteritis only one was found free of otitis, two were unilateral and five bilateral.

In the chronic enteritis (where the symptoms had persisted more than fourteen days), complicated or not with pneumonia or severe respiratory disease, there were 26 cases and only one of these proved to be free of otitis. Another interesting feature connected with the autopsies of this group was that where the complicating pneumonia was considered most positively the cause of death, the autopsies showed an unexpectedly severe condition of the gastro-intestinal inflammation or a surprisingly slight disease of the lungs, but with one exception all showed otitis media and 21 of the 26 showed this otitis to be bilateral and purulent. In the eight cases where the cause of death was given as uncomplicated otitis media the diagnosis was confirmed by the autopsy. The same was the case in those complicated with acute bronchitis. In only one of the 16 cases of tuberculosis, a ten-months-old boy, was otitis absent. In the other 15 cases there was otitis, some purely mucous and some purulent. In two cases, a two-months-old boy and a boy three and one-half years of age, the otitis was upon one side only. In the other 13, ranging in age from four months to three years, it was upon both sides.

The two subdivisions of Group 10 include chronic pulmonary tuberculosis, four cases, and 12 cases of chronic tuberculosis with acute generalization (acute miliary tuberculosis). The three cases of congenital syphilis were all under four months of age, and the cause of death in each case was considered to be a low constitutional vitality without any special symptomatology beyond this; but in all three of these the otitis was upon both sides and purulent.

In the face of these facts it seems to me we cannot conscientiously attend any grave disease in children without the most careful examination as to the condition of the ear. This is troublesome under the circumstances of light and diet, and ignorance and carelessness, and well-known faultiness of food. It is troublesome to make these examinations, and except as a preparation for better work in the future, it will be for us useless to make them if we do not know enough to recognize disease of the ear drum when the membrane is unruptured; but by conscientious exercise of the technique, one with eyes to see can become expert. In the light of the information presented in this table of Ponfick's, otitis media exists in such an astounding proportion of children's diseases that it is our duty to learn to make these examinations. It is as much our duty to examine the drum membrane as it is our duty to examine a rash upon the skin. Physicians from the time of Hippocrates have looked at people's tongues and learned next to nothing by doing so; and we can certainly learn to look at the tympanic membrane when we have ground for such a hope of saving great numbers of lives.

And now in accepting the responsibility, the unpleasantness, and the discomfort of habitual examinations of the infantile ear in almost every infantile disease, we do not have to be guided by whim or blind empiricism, for we can easily bring to our support substantial, sound, scientific theory, if not absolute conviction. The middle ear is a chamber of most delicate construction, with numerous recesses, processes and angles, lined with the most delicate and absorbent of tissues, its walls rich in a network of nerves, blood-vessels and lymph channels, more intimately connected with the central nervous system than any other extra-cranial portion of the body, and in easily comprehensible connection with the gastro-intestinal and respiratory systems. It is easy for us to understand how this chamber can become infected through the Eustachian tube, easy to understand how, once infected, an inflammation can be excited which will close this Eustachian tube. The infection once established, this chamber is readily turned into an incubator for bacterial growth and a generator for the production of bacterial toxins. The natural process of infant feeding, especially the most natural, the mother's breast feeding, the sucking, causes the greatest possible tendency to the paroxysmal opening of the Eustachian tube, through which bacteria may be expelled into the postnasopharyngeal space and with the next breath to be taken into the lungs or with the next swallow to be taken into the stomach. The middle ear being affected and the exit being prohibited or impeded, we have the production of bacterial toxins in a place where they can be readily absorbed into the general circulation, a general toxemia be produced, influencing any concurrent or accidental ailment in any other portion of the infant's body. This all seems to me so reasonable, so absolutely incontrovertible, and so substantiated by actual facts, that I insist it is our duty as general practitioners, as specialists in pediatrics, to give this matter our daily and most conscientious attention. I will cite but a few cases to show the varied conditions in which we in Calumet have found these observations to be worthy of the trouble of making, but I would assure you that in no case have we regretted the time or the trouble given to them.

These cases are selected on account of the varying conditions. The number can doubtless be multiplied in the practice of any busy general practitioner.

CASE I. A. K., male, age five months. First day: Temperature, 99.8°; pulse, 100. Frequent vomiting: watery diarrhea which had been gradually increasing for past two weeks. Baby bottle-fed from six weeks of age. Condition apparently not grave and ascribed to faulty preparation of food and irregular feeding. Treatment principally correction of diet. Second day: Condition unchanged. No apparent tenderness about the ears, but careful examination of the tympana not made. Further effort made to correct errors in diet. Colon irrigated with water at 70°; bismuth every hour. Third day: Convulsions and death. During life no examination of the tympana of this child was made and the general appearance of the child had not been such as to excite any grave apprehensions. After death, with my associate, Dr. A. B. Mills, I examined the ears. The left tympanum was found tense, and on puncturing clear fluid was liberated. The right tympanum was tense and bulging, and on puncture thick pus poured out. The impression this post-mortem examination made upon my mind was that if these ears had been punctured a day earlier the child would have recovered promptly.

CASE II. G. M., male, age nine weeks, was brought to the Calumet Hospital with history of having been crying continually for fifteen days excepting only when drugged with gin or soothing syrup. Temperature normal, pulse almost imperceptible, bowels constipated. The ears were examined by five physicians, including myself, and we were unable to discover any abnormality in color of the drum membrane, and a bulging in the left tympanum was so slight as to leave doubt of the tympanum being distended with any fluid. Puncture, however, was made, three or four drops of pus liberated, and a solution of cocaine ordered to be dropped into the ear. Before the cocaine solution, however, could be brought from an adjacent room the little patient fell into a peaceful sleep. His mother said it was the only natural appearing sleep he had had in fifteen days; that during these past fifteen days when he slept it was with his eyes and mouth open and his features so pinched and drawn that he looked worse than when he was crying. This sleep lasted over two hours, when he awoke, took the breast heartily, and then went to sleep again and did not awake for eight hours, and from that moment has been in perfect health.

CASE III. R. D., female, age seven weeks. Continuous vomiting for three days. Temperature 105°. Coughing and crying frequently, the cough always exciting crying. No tenderness on pressing the palm of the hand against the external ear. Owing to the smallness of the external auditory canal, examination exceedingly difficult. Puncture was made, however, and scarcely more than a drop of pus liberated from each tympanum. Twenty-four hours later the mother described the child as absolutely well, nursing and sleeping naturally. Temperature 98°.

CASE IV. In the service of my associate, Dr. W. K. West. L. T., male, age eighteen months. Bronchopneumonia with diarrhea for two weeks. This is the fourth attack this child has had. Had been weak and sickly most of the time since birth. There were no ear symptoms, but puncture of both membranes was made on account of the physical signs being not extensive enough to account for the evident gravity of the child's condition. Profuse discharge of pus resulted from one ear, a very slight discharge from the other. There was immediate relief to the restlessness and pain of the child, within twenty-four hours complete convalescence was distinctly established, the cure was perfect, and there has been no outward symptom in the child's rapid development since that time, although this was nearly a year and half ago.

CASE V. M. H., female, age five weeks. Nursing. Apparently no pain, but profuse watery diarrhea and rapid emaciation from only three days' illness. Puncture of right tympanum liberated two or three drops of pus and immediate amelioration of the diarrhea followed, although no medicine whatever was given, and no change in diet.

It should be remembered that our earlier teaching has led us to neglect the ear except in cases presenting ear symptoms. Ponfick's presentation of the subject has demonstrated the absolute unreliability of this policy of waiting. While in his 100 cases it was shown that the ear drum had previously ruptured in eight cases, that is, eight ears, 91 per cent. of all the cases examined had shown middle-ear inflammation, and in only 14 of these was the inflammation limited to one ear, and in 77 cases the inflammation was bilateral, representing 154 tympana, making, in addition to the 14 others, 168; that is, spontaneous rupture had occurred in less than nine per cent. of all the cases of otitis. Presumably also nearly all of these cases excepting those in Groups 8 and 9 were without any symptoms of ear disease.

In regard to the technique of this examination, all I can say is that the utmost endeavor should be made to get the best possible light (an artificial light), with the head mirror and an assorted nest of specula, and that the ear of the infant, being different from that of the adult in the shape of the external auditory canal, should be drawn downward and outward instead of backward and upward, and if the external canal be obstructed by dirt, cerumen, or anything else, it should be carefully washed and the effort at examination resumed. Nothing but long-continued practice will suffice to give one a definite idea of the appearance of the tympanic membrane either in health or in disease, but the practice should be persisted in, for there is nothing about it to prevent any practitioner with eyes becoming as expert in this examination as the most cultured aurist. The fact should be reiterated again and again that in very many cases there is no abnormal appearance to the exterior of the tympanic membrane, and yet the middle ear may contain pus and be the source of a toxemia threatening the life of the patient. It is important also to remember that an incision made carefully in the lower posterior quadrant of the tympanic membrane is wholly free of danger and will frequently reveal a case of grave disease and at the same time be the means of almost instant relief. Thorough cleansing of the ear and douching it with sublimate solution should be done before the puncturing, and ether or chloroform anesthesia induced for a thorough examination.

Since reading this paper at the annual meeting of the Upper Peninsula Medical Society, I have read with much interest a valuable article in the *Philadelphia Medical Journal* of August 5, 1899, by Dr. J. S. Meltzer, of New York. It but adds to my conviction, which is more and more confirmed by my increasing experience in practice, that the proper application and appreciation of this contribution of Ponfick's will result in the saving of great numbers of lives and the amelioration of much suffering.

Medical Progress.

RECENT PROGRESS IN GENITO-URINARY SURGERY.

BY F. S. WATSON, M.D., AND PAUL THORNDIKE, M.D., BOSTON.

ANOMALIES OF THE RENAL BLOOD-VESSELS.

M. E. MICHELEAU [1] describes the following anomalies of the renal blood-vessels, which occurred in 16 individuals examined post mortem.

(1) Three renal arteries to the right kidney, the middle one — the largest — entering on a level with the hilus; the others at either end of the kidney directly into the parenchyma. The artery on the left side and the veins of both sides were normal.

(2) The hilus of the left kidney was situated on its anterior aspect. On this side there were two renal arteries, both springing separately from the aorta. One entered the kidney on a level with the hilus, the other, the parenchyma, at the lower pole of the kidney. On the same side there was also a second renal vein, which emptied into the upper part of the iliac vein of that side. The renal artery of the right kidney was normal, but there were two renal veins, one in front and one behind the artery.

(3) One kidney's blood supply normal. The other was supplied by three arteries, springing separately from the aorta. Before reaching the hilus each of the vessels gave off two branches; in the case of the lower one of the arteries these branches passed behind instead of in front of the renal vein.

(4) The right kidney was supplied by two separate arteries. The lower of these two entered the kidney on the level of the hilus; the other, which was given off separately from the aorta, entered the parenchyma at the upper end of the kidney, and did not send off any branches before doing so. Other kidney's arterial supply and the veins of both organs were normal.

(5) A similar condition to the last case, except that the second or supernumerary artery was below instead of above the principal vessel.

(6) On the left side there is a normal renal artery, but from its stem at a short distance from its origin in the aorta a small branch was given off, which passed to the anterior surface of the kidney and entered its parenchyma there. On the right side a similar condition was found, except that the small artery after passing through a portion of the mesentery finally entered by several branches the suprarenal capsule. The veins of both kidneys were normal.

(7) On the right side a single renal artery springs from the aorta opposite the third lumbar vertebra, and divides into two branches before reaching the kidney at the hilus. Two renal veins at the upper end of the hilus, in front a large vein which passes in front of the upper branch of the renal artery and enters into the vena cava just above the point of origin of the renal artery in the aorta. At the lower end of the hilus there are two small venous branches, one from the front of the hilus and one from behind it, which unite in one vein. The vein formed by this union passes at first behind then in front of the renal artery, and enters the vena cava a little below the point of origin in the aorta of the renal artery. On the left side is an artery which springs from the aorta four centimetres below the point of origin of the right renal artery. This vessel divides into two branches before reaching the kidney. At half a centimetre from the point of origin of the main branch in the aorta, a second supernumerary artery is given off from the aorta also. The vessel is small and passes directly to the upper pole of the kidney, where it enters the kidney parenchyma. There is a single renal vein which is formed by two branches which spring from the hilus between the two arterial stems, and after having formed a plexus with the spermatic, it enters by a single trunk the inferior part of the vena cava.

(8) Each kidney is supplied by two arterial trunks, which are given off from the aorta in separate branches, one pair a little above the other. On the right side the upper of the two branches divides before reaching the kidney into two sets of branches, one passing in front of the upper part of the hilus and one behind it, to enter the kidney; between these sets of branches, passes a branch of the renal vein. The lower of the two main vessels passes nearly to the hilus without branching, then divides into three short branches, which enter directly the parenchyma of the kidney at the lower end of the hilus. The single vein is formed by three branches uniting just within the hilus. On the right side the upper of the two main arteries divides near the hilus into three branches; one passes behind, one above and one in front. The lower of the two main vessels divides into two branches, which approach the lower extremity of the hilus; one passes backward and one forward. The single renal vein is formed from a complex venous plexus of small branches of the renal vein and the left spermatic vein placed in front of the arterial branches.

(9) A single renal artery is on the right side and three renal arteries on the left. On the right side the artery is normal, but the vein is peculiar in that it is formed of two sets of branches, one originating from the posterior and one from the anterior aspect of the hilus. These two sets of branches remain distinct nearly to the vena cava; there they unite into one trunk. The left kidney is supplied by three arteries. Of these, the upper two emerge from the aorta by a common trunk, but separate into two branches immediately; the upper, a small one, passes directly to the renal parenchyma of the upper end of the organ. The second, or lower of the two, passes to the parenchyma of the upper half of the kidney, entering it at the anterior aspect of the hilus; it has three collateral branches. The third artery terminates by four branches near the posterior aspect of the lower end of the hilus, one of the four branches passing to the lower extremity of the organ. The vein is normal.

(10) There are three renal arteries on the right side.

RUPTURE OF BLADDER IN A PATIENT WITH STRICTURE.

Michel and Grosse [2] report this case. The patient was fifty-three years old. Gonorrhea, twenty years previously, not treated. For the past two years marked difficulty of urination; ten days previous to entering the hospital complete retention; partial retention for the five following days, small quantities of bloody urine being passed. He then had a sudden pain in the lower part of the abdomen; vomiting followed; symptoms of peritonitis soon occurred. On examination an impas-

[1] Annales des Maladies des Organes Genito-urinaires, August, 1890, p. 879.

[2] Annales des Maladies des Organes Genito-urinaires, September, 1890, p. 970.

sable urethral stricture was found. On the tenth day edema of the lower part of the abdominal wall. Suprapubic cystotomy and drainage. The patient died a few hours later.

Autopsy shows general peritonitis, and a large quantity of bloody urine in the pelvis. On the left lateral aspect of the bladder, below the peritoneal reflection, there was a complete rent of the bladder of the size of a quarter of a dollar. The adjacent peritoneum had been perforated secondarily by the pressure of the gradually increasing quantity of the fluid. The rarity of this accident occurring in connection with stricture is its most interesting feature.

OBSERVATIONS ON THE DETECTION OF SMALL RENAL CALCULI BY THE RÖNTGEN RAYS.

Robert Abbe [3] has collected 27 cases, including two of his own, in which operation verified the presence of stone detected previously by the radiograph.

The term small, used to describe the calculi in the title, is hardly warranted, as will be seen by the following, quoted from another part of the article: "It will be seen from the reports that stones of various sizes *down to one-half inch* in the largest measurement have been unmistakably shown."

The writer notes the importance of certain points in the technique of the radiographic work as follows: "As essential to success are delicate and fresh sensitive plates. The fluoroscope is useless. Rubber tissue should be interposed between patient and the plate to prevent perspiration damping the paper. The photographic plate must be placed well up against the patient's back, including the last four ribs."

With regard to the machine and the tubes, whatever will make a good bone shadow quickly will make a shadow of the calculus. In the radiograph of the normal loin there should be no shadow of the kidney substance, muscles, fascia, intestines, which should resemble in any way the shadow of a renal calculus. Both experimentally and clinically it was shown that shorter exposures than ten minutes or less gave better results than longer exposures. The impression of easily penetrable stones, such as urates, was stronger with very short exposure. A plate while wet may show nothing, but when dry and held in a proper light shows good results. A thin plate showing nothing when looked at in broad daylight may give a good picture when held in front of a brightly illuminated sheet of clean paper. A thin plate will often display shadows when moved rapidly from side to side under proper illumination, though it has shown nothing when held still. A dense plate that seems impenetrable will sometimes show perfect results when illuminated correctly, either by direct or reflected sunlight with a proper screening of the observer's eye. A properly closed box, like a fluoroscope, adapted to the size of the picture, allows a more correct interpretation of shadows. The negative itself will give more information than the photograph.

ANASTOMOSIS BETWEEN BLADDER AND URETER.

Sokoloff,[4] of Moscow, reports 28 cases with one of his own, and describes his procedure most clearly. Two illustrations show method of incision and manner of joining the ureter and bladder. The operation is advocated in cases of ureteral fistulæ.

[3] Annals of Surgery, August, 1899, p. 178.
[4] Deutsche Zeitschrift für Chirurgie, June, 1899, p. 185.

OPERATION FOR ECTOPIA VESICÆ.

Sonnenburg [5] recommends the removal of the bladder and the insertion of the ends of the ureters into penis. He describes his operation, and reports seven cases, with no death. Sonnenburg thinks that plastic operations are well-nigh useless, for, although they can readily be performed, the resulting bladder has no retaining power, and also predisposes to the formation of incrustations which carry pain and danger with them. He advocates (and has done so since 1882) the insertion of ureters into penis, as putting them into the bowels makes a pyelonephritis quite probable.

EXPERIMENTAL STUDIES IN LIGATURE OF RENAL VESSELS.

Alessandri,[6] of Rome, has published a long and carefully prepared article in which he reviews the beginnings of renal surgery, reports many cases and much literature bearing upon his subject, and finally describes with much detail his own experiments upon dogs and cats. His conclusions are briefly as follows:

(1) That ligature of the renal veins is not incompatible with the life and activity of the kidney, but that it offers serious *immediate* danger to life of the animal. If animal lives, a collateral circulation develops sufficiently to re-establish the renal function.

(2) That ligature of the renal artery in the cat does not allow the same restoration of function as in the case of the dog. In the latter there results a good collateral circulation which suffices for the health and proper activity of the organ. In man the presence of many possibly collateral arteries offers a good chance for a similar collateral circulation, in the author's opinion.

(3) That the ligation of all vessels (veins and arteries) is incompatible with life and functions of the organ, but that there is enough collateral circulation in this case to prevent any form of rapid necrosis, and there results a gradual cirrhosis instead.

ARTERIAL CIRCULATION OF THE KIDNEYS; ITS IMPORTANCE IN SURGERY.

Zondek [7] contributes a careful study based upon maceration preparations of 15 kidneys, illustrations of which accompany the article.

RESECTION OF NERVES FOR NEURALGIAS.

M. Rochet [8] reports three cases at the French Association of Urology, where the perineal nerve (perineal branch of internal pudic nerve) was successfully resected for painful urethrocystitis. Relief of patient. Internal pudic nerve was cut down upon where it passes out through small sacrosciatic notch.

Donath and H. Hüttl [9] report a case where six to seven centimetres of the "lumbo-inguinal" and "external spermatic" nerves were removed for neuralgia of testis, which followed an attack of gonorrheal epididymitis. Relief for four months; then recurrence of pain. The nerve was approached through an incision like the one for exploring the ureter.

CAUSE OF NEPHROLITHIASIS.

Ikawitz[10] discusses six cases of lithiasis, which he says is really a secondary process. He thinks the trouble begins as an "endonephritis" which term he gives to the inflammation of the epithelial lining of glomeruli, tubules, and pelvis of the kidney. He thinks the lithiasis is directly secondary to this "endonephritis."

TORSION OF THE SPERMATIC CORD.

Sasse[11] reports another interesting case, illustrating the results of interrupted circulation in the testicle. A purely clinical article and an interesting one.

ANURIA OF LONG DURATION.

Dunn[12] and Doebbelin[13] report cases of long continuing anuria, the former one of ninety-six hours' and the latter one of eight days' duration. Both were due to calculi. In the former case the patient recovered without operation, while in the latter case the stone was found in the ureter and was pushed down into the bladder, from which it was expelled by the patient during convalescence.

GONORRHEAL PERITONITIS IN CHILD.

There are many recorded cases in children where an ophthalmia due to the gonococcus has been followed by joint involvement. Braquehaye[14] reports a case of gonorrheal peritonitis followed by an arthritis in both ankles.

PROSTATE — CLINICAL NOTES.

Two clinical papers worthy of attention are the following:

(1) Fenwick,[15] "Clinical Notes upon the Rectal Contour and Consistence of a Thousand Prostate Glands."

(2) Wolff,[16] "Ueber die bösartigen Geschwülste der Prostata insbesonders über die Carcinome derselben."

The former tabulates the author's large individual experience with such examinations, and the latter deals in a most careful and complete way with the whole subject and literature of cancer of the prostate.

Reports of Societies.

FIFTH DISTRICT BRANCH OF THE NEW YORK STATE MEDICAL ASSOCIATION.

FIFTEENTH ANNUAL MEETING, HELD IN BROOKLYN, N. Y.

MALIGNANT DISEASE.

THE discussion was opened by the President, DR. JOSEPH D. BRYANT, who spoke first of the exceptional amount of attention which this subject was now receiving from the profession. To a large extent, he said, it had taken the place of tuberculosis as a topic of discussion. In the latter affection a solution of the problem had been reached, but this unfortunately was not the case as regards malignant disease. The subject was still surrounded with gloom and direst apprehension, and he felt convinced that one of the principal causes of this was the hesitancy on the part of the physician as well as the patient and the friends of the latter to recognize the extreme importance of the most prompt operative interference. Whatever light scientific investigation might in the future throw upon the matter of treatment, there could be no doubt that at the present time our only chance of success lay in an early operation in every case possible. The necessity for this was evident when the undoubted rapid increase of malignant disease was taken into consideration.

Dr. Bryant quoted Dr. Park's ominous prophecy that in ten years from now cancer would cause more deaths in New York than pulmonary tuberculosis, small-pox and typhoid fever combined, and said that while this might be considered an extreme view, there could be no question of the increase of this form of disease not only in the United States but throughout the civilized world. He then proceeded to recount the latest available statistics from New York, Boston, Chicago, Philadelphia, San Francisco, Baltimore, New Orleans, London, Paris, Berlin, Vienna, Munich and Hamburg. Having mentioned the conclusion of Newsholme that the increase was not a real but an apparent one, due to more careful diagnosis and more frequent autopsies in recent years, he said that whether this was the case or not there could be no doubt that cancer was one of the most formidable diseases with which we had to contend. The latest statistics showed that it caused 5.06 per cent. of all deaths in persons over forty-five years of age.

What, then, could be done to arrest its progress? The other great scourges of the human family were either now well held in hand or on the eve of coming under control. Billings had directed attention to the fact that in the course of years the parts of the body most frequently attacked by cancer had materially changed. Thus, the digestive organs were now much oftener the seat of the disease than formerly. In males the mouth and throat were very frequently attacked, but this was not so generally the case in females. Inasmuch as in the middle period of life, from the age of forty-five to that of fifty-five, the cases of cancer were more numerous than in all other periods combined, it seemed reasonable to assume that malignant disease did not derive its origin from preceding causes; for surely the first forty-five years of life was the time of greatest activity and exposure. It might, perhaps, be claimed that the *inception* of the disease occurred in earlier life, and that it only became fully developed in the later; but it was impossible for any one who was familiar with the persistent, progressive and aggressive character of cancer to accept the proposition that it could remain latent in the system for any length of time. The age at which the disease commonly occurs would, therefore, seem to present a strong argument against its parasitic origin.

As to the treatment, there could be no question that a prompt and thorough operation was called for in every possible case and it was of the utmost importance that the lymphatic connections of the tumor should be completely removed, whether they were known to be implicated or not. It was, in fact, often

[16] Deutsche Zeitschrift für Chirurgie, September, 1899.

impossible to state whether the neighboring glands were or were not involved. Manipulation was misleading and unreliable, and it should constantly be borne in mind that these glands always became to some extent affected before they were appreciably enlarged. The surgeon who failed to empty the axilla when excising a cancerous breast was grossly neglectful of his patient's welfare. Gross had found that when the axillary glands were affected, the suprascapular glands were also implicated in over six per cent. of cases. The point which he wished to emphasize was, that the discovery of the existence of a tumor in any part of the human system demanded that the character of the growth should be determined at the earliest possible moment, and that just as soon as the presence of malignant disease was established it should be removed in the most thorough manner. Unfortunately, however, it was too often the case that hesitation and delay characterized everything but the growth of the tumor. Still, great progress had been made since 1870, when Sir William Paget declared that, as far as he was able to ascertain, no permanent recoveries had ever resulted after operation; and already in 1880 Gross had shown that with improved surgical technique the percentage of cures was 9.05. In conclusion, Dr. Bryant quoted the much better results collected by Bull in 1894, and the still more favorable figures given more recently by Halsted and Watson Cheyne. The mortality from the actual operation was now but from two to three per cent.

DR. EDWARD K. DUNHAM read a paper on

THE NATURE OF MALIGNANCY IN NEOPLASMS.

Formerly, he said, hematomata, retention cyst and granulomata had been regarded as neoplasms, and while the essential character of a neoplasm had now been more definitely determined, there was even yet some difference of opinion in regard to the matter. In order to understand the subject clearly it was necessary to study the formation of the various tissues in the development of a new individual. We had (1) cells, and (2) intercellular substances. Cellular activities were of three varieties: (1) nutritive; (2) reproductive, and (3) formative, resulting in differentiation into various tissues. At this point two very important characteristics were developed: (1) specialization, and (2) allegiance to hereditary control. He then proceeded to apply these elements to morbid processes. Inflammation, he said, was one of the results of damage to tissues. The effects of the damage were of four kinds: (1) total destruction; (2) necrosis; (3) degeneration, and (4) irritation. One of the results of irritation was a revival of the processes met with in the normal development of tissues, and a definite purpose was accomplished. As illustrations he mentioned (1) multiplication due to persistence of the damage, as seen in tuberculosis; and (2) deviation resulting from the existing conditions. In the true neoplasmata the tissues did not develop to meet any definite purpose having direct relation to the formation of special tissues. The cells retained their nutritive and formative properties, but not the reproductive, and clinically the growths were known as benign.

In the most malignant tumors, such as sarcoma, we had reproductive activity and nutritive activity, but the normal activity of the tissue cells was almost, if not totally, lost. Rapidity of growth and metabolic activity were characteristic of such tumors. There was a tendency to implicate surrounding tissues. Infiltration and a liability to metastasis were met with. Intermediate between sarcoma and benign tumors there was a considerable number of various kinds of growths. The malignancy they displayed was proportionate to the loss of formative activity in their cells. The view here set forth, Dr. Dunham said, was by no means universally accepted. He then referred to Sanfelice's contention in favor of blastomycetes, and stated that while not prepared to deny that the presence of parasites might possibly divert the cells from their normal allegiance, his own observations led him to doubt that such was the case, He was furthermore convinced that it was impossible to draw a definite line between benign and malignant growths.

DR. L. GRANT BALDWIN read a paper on

MALIGNANCY IN THE FEMALE GENITO-URINARY SYSTEM.

He said that out of 3,787 gynecological cases of which he had records, there were 60 showing some form of malignant disease. There were two cases of cancer of the bladder and urethra, three of cancer of the ovaries (in one of which only a single ovary was affected), and 55 cases of cancer of the uterus. In 17 of the latter hysterectomy was performed, and four of the patients were in good health to-day. Fifty-six of the 60 women were married, and with but a single exception all had been pregnant one or more times. Procreation would, therefore, seem to be a powerful predisposing cause of malignant disease. Out of the 50 women suffering from cancer of the uterus, only one had never been married or pregnant. Laceration of the cervix was beyond dispute a very frequent factor in the causation.

In his experience the prognosis was very bad. The fault was largely that of the family physician and the patients themselves. In nearly all his cases when the patient was first brought to him the disease had already existed from six months to two years; while in such an affection as this, our only hope lay in early and complete removal. There was, unfortunately, a widespread misapprehension in regard to the subject on the part, not only of the public, but of medical practitioners. It had long been a prevalent idea that profuse and prolonged uterine hemorrhage was a natural circumstance at the time of the menopause. The occurrence of hemorrhage, however, whether at the menopause or any other time, was the one thing of all others which should call for a prompt and thorough physical examination. The fact of the absence of pain was misleading; for in cancer of the uterus pain was by no means an important sign. As to loss of flesh, this, like the pain, was apt not to occur until late in the disease, after metastatic changes and systemic infection had taken place. The presence or absence of odor was also an unreliable sign, and the cancerous cachexia, on which so much stress had been laid, came at a period when it was generally too late for the surgeon to be of any material service to the patient. A thin watery discharge from the vagina sometimes preceded the occurrence of hemorrhage, and the appearance of this should always excite suspicion. The continuance of menstruation, even if the flow was not profuse, beyond the normal time for the menopause should also arouse suspicion.

In regard to the subject of treatment he would only say that in uterine cancer an early and complete removal, preferably by vaginal hysterectomy, was by all

means advisable. As to the matter of technique, if we could do away entirely with sutures and ligatures it would be a great step in advance, and the use of clamps or forceps was therefore to be preferred. The author especially commended Dr. J. S. White's instrument, and also spoke favorably of Skene's electric hemostatic forceps.

DR. JONATHAN WRIGHT read a paper on

MALIGNANT DISEASE OF THE NOSE AND THROAT.

He said that as regards the nose there appeared to be a few exceptional cases in which the patient recovered without the removal of the growth by operation. Whether these were only apparent exceptions, and due to errors in microscopic examination, he was unable to say. The conditions met with in the nose presented a very different clinical picture from those of the larynx. There were very few cases of pure adenoma in the nose, adenoma being more often combined with carcinoma or epithelioma, and sometimes with sarcoma. These neoplasms were usually of slow growth, and would seem to be favorable for operation, but, so far as his experience went, they were apt to occur in very old persons, and the difficulties of operation were often very great. Clinically there was very little difference between adenosarcoma and adenocarcinoma. Sometimes the granulomata of syphilis strikingly resembled round-cell sarcoma, the most malignant of tumors. In doubtful cases it was always well to bear in mind the possibility of syphilis, and to subject the patient to a course of iodide of potassium by way of test. As to "clinical sense," so much relied upon by some, the greatest watchfulness should be maintained lest it should lead the observer into error.

In malignant disease of the fauces there were fewer cases in which the diagnosis was for any length of time attended with doubt, although it was sometimes difficult or impossible to secure a fragment of the growth for microscopical examination. Sarcoma of the tonsil was not a very rare form of trouble, and sometimes it was quite difficult to make the diagnosis between this and simple or syphilitic hypertrophy, although the latter was rare. The consideration of malignant disease of the larynx had to be omitted on account of lack of time.

DR. MAX EINHORN read a paper on

THE EARLY RECOGNITION AND MANAGEMENT OF MALIGNANT DISEASE IN THE DIGESTIVE SYSTEM.

The achievements of modern surgery, he said, showed that cancer is primarily a localized, and not a systemic, disease. Judging from analogy, malignant tumors, if discovered early enough, were just as successfully removed from the digestive tract as elsewhere, and it should therefore be the aim of the clinician to perfect his diagnostic ability with regard to this form of disease. The stomach tube in conjunction with the chemical analysis of the gastric contents had marked a decided advance in this direction, and transillumination of the stomach might also, in favorable instances, be of some service; but still our methods were as yet comparatively crude, and as a rule afforded a recognition of the malignant affection only at a stage when it had already progressed to a considerable extent. In speaking on the subject of etiology he said that one factor which, although it was not directly concerned in the origin of cancerous tumors, created a decided predisposition for their development was repeated irritation. Hence, those parts along the digestive tract which were subjected to the most marked mechanical irritations were also most often the seats of malignant disease. Thus, the stomach, receiving the food in a comparatively coarse state, was the organ most frequently attacked, and here, again, the cardia, and especially the pylorus, were chiefly involved. The small intestine, through which the chyme passed in its greater part in liquid form, was very seldom attacked with cancerous disease, while the larger intestine, in which the fecal matter assumed a more solid consistency, showed a comparatively large percentage of cases of this kind.

Dr. Einhorn described the conditions under which the diagnosis of cancer of the different parts of the digestive apparatus was justifiable, as follows:

I. *Œsophagus and cardia.*— Gradually developing dysphagia and the presence of a stricture in the œsophagus, especially if a particle of tumor showing the characteristics of cancer has been brought up with the tube, or the presence of the above symptoms in connection with frequent small hemorrhages.

II. *Stomach and pylorus.*— A positive diagnosis of cancer may be made if the following conditions are noted: (1) If particles of tumor are found (in the wash-water or tube) which show the microscopic characteristics of a malignant growth; (2) the presence of a more or less large tumor with an uneven surface, belonging to the stomach and associated with dyspeptic symptoms; (3) the presence of a tumor associated with frequent hematemesis; (4) constant pains, frequent vomiting, ischochymia, emaciation — all these symptoms being constant and not extending over too long a period (six months to one year); (5) tumor and ischochymia; (6) emaciation, ischochymia, presence of lactic acid; (7) constant anorexia and pains, not yielding to treatment, accompanied by frequent small hemorrhages (of coffee-ground color).

III. *Large and small intestines.*—(1) The detection by abdominal or rectal palpation of a tumor in the large or small bowel, together with symptoms of cachexia and disturbances of defecation; (2) the presence of a tumor, as described, and the discovery in the stools of small particles of a neoplasm with cancerous characteristics; (3) gradually increasing disturbances for a few months in a previously healthy person, accompanied by cachexia and symptoms of a commencing or already developed stricture of the bowels, and the presence in the stool of small particles of growth, giving the microscopic appearances of cancer.

It was a thorough examination of the physical state of the patient, strict attention being paid to all the methods applicable to such cases, and a full knowledge of the history, which enabled us to discover the existence of malignant disease at a comparatively early period. Continued observation and repeated examinations were often of service in arriving at the diagnosis, and sometimes examination under narcosis was desirable. In rare cases in which a probable diagnosis of cancer could be made an exploratory laparotomy, with a view to establishing the diagnosis and performing a radical or palliative operation, would be required.

In the treatment the following points were to be observed: (1) Whenever the tumor is accessible for operation, and there is the slightest hope of curing the patient, a complete extirpation of the growth should be made; (2) if the tumor is not accessible for operation, or the entire removal of the malignant disease

practically impossible, palliative operations which serve to alleviate suffering and prolong life should be undertaken in suitable cases; (3) cases operated upon, as those left without operation, require for their management a skilful physician, who can lessen suffering and nearly always prolong life even under the most trying conditions. The conclusion of the paper was devoted to the special management of malignant disease in the different portions of the digestive tract.

DR. J. W. S. GOULEY made some remarks on

MALIGNANT DISEASE IN THE MALE GENITO-URINARY SYSTEM.

DR. WM. B. COLEY read a paper on

THE TREATMENT OF INOPERABLE MALIGNANT TUMORS.

He differed from the others taking part in the discussion as to the etiology of malignant growths, regarding them as of parasitic origin. The links in the chain of evidence to support this view, he said, were being slowly forged, and but few were now lacking to complete it. Some of the most striking proofs were afforded by Sanfelice's recent experiments on dogs, an account of which he gave. Having stated that seventy-five per cent. of malignant growths were at some time or other beyond the reach of the knife, he referred to Mander's recent work on the ferment treatment. Among the features of the treatment was the lessening of the amount of animal food taken by the patient, butcher's meat being altogether excluded, and the injection of pure ferments. The results from the use of yeast cells were yet too recent to be of value as to the permanent value of the method. The treatment by injection of thyroid extract and the removal of the ovaries had a logical warrant, as the action of the extract was analogous to that of the pure ferments in breaking up glycogen, and he here referred to cases recently reported by Frederick Pye, Watson Cheyne and others.

He spoke briefly of the use of celandine, of electricity, and of the parenchymatous injection of alcohol in the treatment of cancer, and then took up the treatment by means of the mixed toxins of erysipelas and bacillus prodigiosus. The results obtained from this method during the first four years of its employment he had given in a paper before the New York State Medical Association, published in the *Transactions* of the society for 1895. As stated then, the variety of malignant disease that showed the greatest improvement under its use was the spindle-celled sarcoma. After recounting a number of special cases, he said that the cases now amounted in all to 159. Of 87 cases of round-cell sarcoma 39 showed more or less improvement, and in one instance the patient remained entirely well at the expiration of five years. Twenty-two of the cases were of the spindle-celled variety of sarcoma. Of these, eight remained well at the expiration of from three to seven years, and 11 at the expiration of from one to three years. He had already called attention to the very great difficulty both of obtaining suitable cultures and of keeping them sufficiently virulent. These toxins were very powerful bacteriological products, and it was necessary to use them with the greatest caution in order to avoid dangerous risks. Among the conclusions at which he had arrived were the following: That mixed toxins exert an inhibitory action on malignant growths; that these are less efficient in their action on carcinoma than on sarcoma; that in a larger proportion of cases of inoperable sarcoma the patients survived for more than three years after the treatment; that the action of the toxins in no wise resembles that of a local escharotic.

In summing up the discussion, the President, DR. BRYANT, said that (1) there was no question as to the wide prevalence and formidable character of malignant growths; (2) opinion was at present divided as to the exact nature of such growths, whether they were of microbic origin or the result of perverted cell action; and (3) there was no disagreement as to the desirability of an early diagnosis and, when this was made, as to the necessity for prompt operative action in all possible cases.

Recent Literature.

The Nervous System and its Constituent Neurones. By LEWELLYS F. BARKER, M.B. Pp. xxxii, 1,122, with two colored plates and 676 illustrations in the text. New York: D. Appleton & Co. 1899.

When the publishers' announcement calls a book "the most scientific and complete work on the subject ever published, and one of inestimable value to the practitioner and student of medicine," we usually accept the statement with the same amount of credence that we give to the praises of the administration by the pious editor who wants an office, but the announcement of the present volume from which we have just quoted is true. A small portion of the work was published in the *New York Medical Journal* in 1897, but, although it showed that the book would probably be of value, it gave no adequate idea of its real merit. We have had occasion before to regret the lack of English works on the anatomy of the nervous system which could be compared with such works in foreign tongues as those of Dejerine, Van Gehuchten, Ramón y Cajal, Kölliker, Bechterew, Edinger, and others, but that reproach has been done away by the magnificent volume before us. When we read the author's statement in the preface that there has been no attempt to exhaust the bibliography and that only the more important references consulted have been cited, and compare that statement with the number of references actually cited in the foot-notes, the enormous amount of labor involved in the mere study of the literature may be faintly appreciated; but the book is no mere compilation of other men's work. The work of the independent investigator is apparent throughout, and the statements of others are checked and controlled by the judgment of the observer who is familiar with the subject from practical experience.

Not only may the work be put upon an equality with the treatises we have referred to above from its exhaustive and independent character, but it deals with the subject in a wholly new fashion, widening our conceptions of the anatomy of the nervous system, while at the same time it simplifies the intricacies of the subject in a way that no other work with which we are familiar does. We believe it no exaggeration to say that, since Golgi first introduced us to the new conception of the neurone, no work has yet appeared of such importance. Let there be no mistake, however, in the character of the work. It is not a treatise on the gross anatomy of the nervous system. The

student who wishes information as to the position of the ventricles or the variations in the cerebral fissures and sulci, or even the shape and size of the spinal cord, must seek elsewhere. This volume deals with the finer structure of the nervous system, as made up of its constituent neurones, and with their anatomical relations with one another.

The first section deals with the history of the development of the neurone concept, including a careful study of the arguments brought against it by Apáthy and Bethe. The next two sections deal with the external and internal morphology of neurones, especially as manifested by the staining methods of Golgi and Nissl. The fourth section shows the histogenetic relations of the neurones, with a suggestive chapter summing up our present knowledge of the human body as a segmented organism. The fifth section, on the neurone as the unit in physiological and pathological processes, is of absorbing interest and it merits the closest study of every physician as a most suggestive and enlightening presentation of the processes of nervous and mental physiology as interpreted in the light of the neurone theory. These sections, however, occupy only about three hundred pages. The last section, which forms the bulk of the work, is a study of the grouping and chaining together of neurones in a complex nervous system like that of man and higher animals, or, in other words, of the fine anatomy of the nervous system as exhibited in the anatomical relations of the various chains of neurones having a definite physiological function. This study begins with the consideration of the neurones connecting the sense organs of the body with the central nervous system, then of the neurones within the central nervous system connecting the end stations of these first neurones with other portions of the nervous system, then of the motor neurones connecting the central nervous system with the muscles, the neurones connecting with those which throw them under the influence of other centres, and finally the projection, commissural and association neurones of the telencephalon. The adoption of this method of presenting the facts of nervous anatomy and making it the foundation of classification is the most valuable and most original feature of the book. It was of course indicated in the works of Flechsig and Bechterew, and partially adopted by Van Gehuchten, which renders his treatise on anatomy so valuable to the student, but Barker is the first to make this grouping of the neurones the primary and fundamental element in the study of the anatomy of the nervous system. That there are still enormous gaps in our knowledge and that the exact physiological relations of myriads of neurones are still unknown are patent facts, but we believe that this method, defective as it is and must be for years to come, is the simplest, clearest and most rational way to present the facts of nervous anatomy and physiology to the student, and the way in which he can most easily grasp them and retain them as a connected whole. From what has been already said it is perhaps needless to add that, having adopted this admirable method, the presentation of the facts themselves is equally admirable, showing careful research, sound judgment, and a marvellously accurate study of the literature which seems to have overlooked nothing of importance and little that is unimportant. It would be a task even for the Dean of St. Patrick's, who could write entertainly of a broomstick, to be particularly diverting in dealing with the various tracts of fibres in the nervous system, but, with all the other merits of this work, it would be unfair to make no mention of the charm and clearness of its literary style, which, wherever the material will permit, becomes actually entertaining and delightful — even in dealing with the anatomy of the nervous system! The generous collaboration of the publishers, too, must not be overlooked, for the illustrations, profuse in number and often colored, form a valuable and important feature of the work, and the execution of them, as well as the careful typography, deserves the highest praise.

Cyclopedia of the Diseases of Children; Medical and Surgical. The Articles Written especially for the Work by American, British and Canadian Authors. Volume V. Supplement edited by WILLIAM A. EDWARDS, M.D. Illustrated. Pp. xvi, 1,332. Philadelphia: J. B. Lippincott Co. 1899.

This work is not a general text-book, covering the whole subject in a series of complete classified chapters, but a supplement to the well-known cyclopedia of Keating, the last volume of which appeared ten years ago, and is written with the object of rounding out the information obtained in the earlier volumes, and bringing it up to date.

The book is a collection of independent articles, medical, surgical, clinical and pathological, without attempt at classification, covering the important topics in pediatrics, and including many of general scope and interest. It is a product of eighty-seven contributors, eighty of which have written one article each and no one more than three. The list includes a large number of the best English and American writers.

The result is a book of somewhat peculiar quality. The articles are mostly written with the special design of showing the advances that have been made in pediatrics in the last ten years, and recent additions to our knowledge are made very prominent. Many of the writers adhere rigidly to this scheme, and their success shows what might have been done by all. Some chapters have been reprinted from the original with little or no change. Some have been revised by the original contributors, others are by new authors upon subjects treated in the original work. Some chapters are of great excellence, many are only mediocre and add nothing to existing knowledge. The recent bibliography of the subject is given in many instances. We wish to especially mention the following very excellent articles: Ballantyne on Congenital Disorders and Diseases of the New-born; Rotch on Feeding in Infancy; Hare on Advances in Therapeutics; Peffer on Diseases of the Stomach; Barlow on Scurvy; Osler on Cretinism; Musser on Diseases of the Liver; Howard A. Kelly on Diseases of the Ovaries and Tubes; Sachs on Amaurotic Family Idiocy; Snell on Hygiene of the Eye; Cheadle on Rheumatism; Sherman on Tuberculosis of Joints.

We believe that certain articles could well have been omitted as belonging to books dealing with clinical methods or general text-books of surgery. On the other hand, in considering the advances in knowledge of the infectious diseases, we are surprised to find meningitis omitted. Pediatrics is of course closely allied to general medicine, but we cannot help feeling that a few of the articles were written too much from experience with adults.

The illustrations are numerous and well executed. We must draw special attention to those in the articles on Feeding, Bicycling, Cretinism, Hernia, Appendicitis and the X-rays. The book is well printed and bound and the index is clear and complete. All in all, the book is a valuable one, containing much that is new, and no owner of the original cyclopedia will now consider it complete without the addition of the present volume.

A Text-Book of Mental Diseases, with Special Reference to the Pathological Aspects of Insanity. By W. BEVAN LEWIS, L.R.C.P. (Lond.), M.R.C.S. (Eng.), Medical Director, West Riding Asylum, Wakefield. Second edition. Pp. xxvi, 609. Philadelphia: P. Blakiston's Son & Co. 1899.

It is particularly disappointing that such an able and original observer, investigator and writer as Dr. Lewis, who throws so much light on a number of points which his predilections lead him to treat at length, should not go farther and cover the whole ground of mental disease in a sufficiently full, advanced and symmetrical treatise on the whole subject. As it is, in spite of the much-needed additions and changes in the second edition of his text-book, which make it a decided improvement over the first, there is enough lack of system, proportion and completeness remaining to render it unsatisfactory in many particulars. The chapters on Alcoholism, Epileptic Insanity, Progressive Systematized Insanity, and much of that on General Paralysis, for example, are valuable contributions to our knowledge, but a work on insanity which gives in varying amount of detail the etiology of a few varieties and entirely omits it in other and important ones; in which there is no allusion to the rôle of syphilis in general paralysis, or any other form, for that matter; which contains no reference to classification, diagnosis, the method of examining patients, feigned insanity, or confusional insanity, cannot reasonably be expected to properly meet the needs of students, instructors, or practising alienists.

The chapters on Minute Anatomy and on Pathology show, as might be expected, genuine scientific research of the highest order, and before one can safely criticise the author for clinging to his views as to the existence and office of the "scavenger cell" in the face of more recent opinion, he must be sure that other investigators are his equals in close and accurate observation and in sound deductions therefrom.

With all its faults as a text-book, it is nevertheless a highly interesting work, and if in making search for the author's valued views on some special question we are occasionally unsuccessful, we are sure to be beguiled into following some new presentation of another subject, and to profit by his teaching.

The Trained Nurses' Directory. Composed of Names carefully selected by Prominent Physicians and Surgeons of New York and Vicinity from their Private Lists. Compiled and edited by M. LOUISE LONGEWAY, Graduate of the New York Training School, Bellevue Hospital. Sixth edition. 1899.

This small volume of one hundred and thirty pages is designed to furnish a list of nurses who have had an adequate training and are recommended by reputable physicians. After each name is given the line of nursing in which the nurse especially excels, with his or her address. The directory should be of great value to physicians as well as to patients.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JANUARY 18, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE PHYSICIAN AND THE SURGICAL CONSULTANT.

ASEPSIS and the numerous recent refinements in operative technique have, as is well recognized, vastly broadened the field of surgery, and of legitimate surgery, to the great benefit of humanity. For this extension of the scope of surgical art, we have reason to be and are, no doubt, profoundly grateful, yet on careful review of the situation certain facts are observed which indicate that this expansion has brought with it a certain amount of harm as well as good. It is occasionally desirable and salutary to cease congratulating ourselves on the grandeur of modern progress in our art and to contemplate, for our better guidance and the possible benefit of our patients, some of the pitfalls into which the unwary surgeon and consultant may be led.

In the days when all surgical operations were attended with greater danger and suffering to the patient than they are at the present time, the surgeon was in every act and deed of his profession always under grave responsibility. He was justified in operative interference only under definite and serious indications and after a most thorough and careful diagnosis and consideration of all the conditions surrounding the case. Under such circumstances the men who by force of personality and training were fitted to succeed in the profession of surgery were fewer in number than at present, and the question is worthy of consideration whether they were not, on the whole, men of better judgment.

In these days operative interference is so easy, that mistakes as a rule cost less. A legitimate advantage may be taken of this fact to take greater chances for a possibility of relief in serious conditions, and this advantage is taken daily by conscientious surgeons. There is, however, abundant evidence that this principle is carried too far, and that operations, particularly exploratory laparotomies, are undertaken with more prospect of settling a diagnosis than benefiting the patient, and often before more legitimate means of diag-

nosis, including especially those requiring careful observation of the patient over long periods of time, have been exhausted. "Exploratory laparotomy will settle the question so easily and quickly," says the enthusiastic surgeon, "and may afford a means of cure." It certainly may, but there are so many doubtful abdominal conditions which are benefited by exploratory laparotomy neither in regard to diagnosis nor treatment, that no conscientious surgeon will perform it till every other means of diagnosis has been exhausted. Exploratory laparotomy has its legitimate field, but should be limited to cases in which other methods of diagnosis have been tried, and in which some prospect, however slight, of subsequent advantage is presented.

Another occasional cause of unnecessary surgery is found in a wrong attitude of the surgical consultant toward the family physician. The latter is too apt to call a surgeon to see a case, not to take charge of it, but to operate, he having himself assumed the responsibility of deciding upon operation, and told the patient and his friends that an operation ought to be performed. The surgeon sometimes, it is to be feared, in his anxiety to agree with the physician who called him in consultation, may, even if in his own judgment the case is one in which a waiting policy would be better, delude himself into thinking that the physician has had better opportunities to observe the case, and operate against his own better judgment, with results not always for the best interests of the patient. Certain physicians, it is to be feared, would call a surgeon again in consultation who had done an unnecessary operation to the detriment of their patient rather than one who quietly but firmly refused to operate in contravention of their opinion previously expressed to the patient's friends.

If the profession can only remember that surgery is a specialty and that questions not merely of operative technique but of diagnosis and treatment can be settled rightly only by men of experience in surgery, if they would call a consultant to decide upon operation, instead of taking themselves the responsibility of deciding questions the magnitude of which they do not realize, they would get results better for their patients and themselves, and not encourage the growth of a class of surgeons who are willing to act on the physician's opinion even at the expense of his patient, and incidentally to secure a grip on his consultation practice. This state of things is bad for the welfare of the patient, the art of surgery and the morals of every one concerned, and could be easily put an end to by the consultant's leaving to the surgeon the decision.

"Very true," says the physician, "but I don't want to subject my patient to the expense of a consultation unless the surgeon is going to do something. I can't call a surgeon every time there is merely a *question* of operation — I must decide myself." To such the answer must be made, that if he leaves the matter to his own judgment he will call the surgeon often too late to do any good in cases where his assistance has been urgently needed, as well as summon him at times to operate on cases which would better be let alone. It surely should strengthen the position of a physician in an enlightened community to be beforehand in calling assistance in the settlement of difficult surgical questions, rather than to settle them himself and then call a surgeon who will support him in his mistakes if necessary. Absolute honesty toward his patient's interest is all that is required on the part of the physician and the consulting surgeon.

The taking of responsibilities by members of the profession for which they are not fitted by training and experience is the bane of honest medical and surgical practice, and reacts in harm to the community and the medical profession.

Let responsibility be honestly placed and not wrongfully assumed in the relation of the physician and the consulting surgeon, and good surgery will be promoted at the expense of rash and careless work.

ORIGINAL RESEARCH: A MEANS OR AN END.

It is becoming clear that the medical school of the future, which will most completely fulfil its function as a centre of liberal scientific education, must be associated with a university. This is desirable from many points of view, but particularly because we need in medicine the broadening influence which comes from close contact with other branches of learning. It is to be hoped that as time goes on the bonds between the parent university and its dependent schools may continually become closer, in order that research, so important an element in higher education, may the better be subserved.

In his recent address as President of the American Society of Naturalists, Prof. W. G. Farlow, of Harvard University, has drawn attention to certain facts in the government of our American universities and in their attitude toward research which deserve comment. He finds a decided difference, in the first place, between the government of American universities as compared with that of Germany, and notes the fact that in spite of the circumstance that we are living in a republic, the tendency in our institutions is toward a more autocratic form of government, whereas in Germany it is of a more democratic character. With us the president and various governing boards are the guardians of the policy of the university, while in Germany the members of the instructing body have a far more definite voice in matters of policy and appointment.

The American system has led, indirectly perhaps, but none the less surely, to the subordination of original research to practical ends, rather than to its cultivation for its own sake, a situation which we must accept, however much we may wish for a broader scientific spirit.

Professor Farlow speaks rather feelingly on this matter, as follows: "Fashion and the natural ten-

dency to imitate others has, however, done very much for us in recent years in aid of investigation, for, while it may be next to impossible to induce the governing board of a university to spend money on investigation for its own sake, it is a comparatively easy matter to convince them that they must make provision for original work because some other institution has done so and is thereby attracting public attention. If original research can be used as a means for advertising a university, there is no doubt that it will be encouraged, and, fortunately, as it turns out, it is a very good advertisement, even better than victories in athletics. The really successful American universities are those in which the most original work is done. The trouble is that if one looks upon research mainly as an advertising medium, one is apt to demand quantity rather than quality, and to regard the number of papers published annually as the standard of scientific activity."

Research is unfortunately often expensive, and inasmuch as those from whom the necessary money is to come are apt to consider that research is valuable only in so far as it is "practical," we are apt in this country to meet with discouragement in the prosecution of theoretical lines of work of any considerable magnitude. Professor Farlow is speaking of the university in general, but this all applies with peculiar force to medicine and medical research. Admitting the desirability and necessity of original investigation as a means of progress, it is clear that efforts in that direction should not be hampered by a constant appeal to the practical; immediate results are often not to be expected, should not be demanded, and are of little or less than no value when obtained. We grow weary, at times, of the frequently heard remark that this or that piece of work is useless because its immediate practical utility is not apparent. If we were more thoughtful than we often are, we should realize that it is out of these theoretical investigations, undertaken in a scientific spirit, that practical results of the greatest magnitude finally grow. We are entirely in agreement with Professor Farlow in his opinion that: "The great charm of the German university hitherto has been what has been described as the intellectual atmosphere, the prevailing desire of pursuing learning and investigation for their own sake, which, however, does not unfit the Germans for the successful application of science in industrial and practical fields. We miss in our own universities this universal desire for investigation, which is with us confined to a certain number of persons who are very enthusiastic, to be sure, but are in most cases obliged to justify themselves in the eyes of those who do not understand the value of investigation."

There are abundant signs, however, that we are at least approaching the realization of the attitude which has for many years been characteristic of the German university. This will undoubtedly mark a decided step in advance, and is unquestionably an essential of productive investigation.

MEDICAL NOTES.

FAMINE STATISTICS IN INDIA. — The present generation has seen four famines in India, namely, in 1865–66, when, according to the famine commission, a population of 47,500,000 was affected; in 1868–69, when the area involved a population of 44,500,000; 1876–78, when it affected directly and indirectly 58,000,000 souls, and 1896–97, when fully 81,000,000 were touched by the ravages.

THE STUDY OF TROPICAL DISEASES IN GERMANY. — In the Budget of the German Empire for 1900, according to the *British Medical Journal*, there appears for the first time a subsidy for the Institute of Tropical Hygiene which it is proposed to establish in Hamburg. The empire will contribute £1,025 yearly to the maintenance of the Institute, which is to be opened on October 1, 1900.

PLAGUE UBIQUITOUS. — Several cases of undoubted bubonic plague are reported as having occurred in Manila. The population is, in parts of the city, very dense, and the system of sewerage defective; there is, as yet, however, no evidence of a widespread epidemic. Two cases have also occurred at Adelaide, South Australia.

A TOY HOSPITAL. — There exists at Ealing, a suburb of London, as the caprice of a rich man, a toy hospital, to which broken toys may be sent for treatment, and whence they are later distributed to the children of the poor.

INFLUENZA IN BERLIN. — An epidemic of influenza has broken out in Berlin, with a considerable mortality already reported.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, January 17, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 72, scarlatina 38, measles 92, typhoid fever 10, small-pox 1.

DEATHS IN BOSTON IN 1899. — There were 11,167 deaths in Boston last year, as against 10,886 during the year 1898, but the population increased during the same period from 541,827 to 555,057, so that the annual death-rate is practically the same as for 1898, or 20.12 per 1,000 inhabitants. The total number of deaths from zymotic diseases is 1,444, as against 1,470 in 1899. There was a decrease in the number of deaths from cholera infantum, cerebrospinal meningitis, rheumatism, typhoid fever, cancer, consumption and from old age; there was an increase in the number of deaths from alcoholism, croup, diphtheria, influenza, measles, scarlatina, small-pox, whooping-cough, Bright's disease, bronchitis, heart disease, pneumonia and violence. At the present time there is some little diphtheria and scarlet fever in Boston. The number of deaths reported to the Board of Health for last week is 240, as against 272 the corresponding

week last year, making the death-rate for the week 22.5. In Cambridge and Newton diphtheria has not diminished. In Cambridge last week there were about 35 cases. On one day 11 new cases were reported. In Weston schools have been closed on account of this disease.

SMALL-POX IN A SCHOONER. — A schooner, arriving last week from Brunswick, Ga., brought a case of small-pox in the person of the steward. The members of the crew have been vaccinated and the patient isolated. The case is regarded as a severe one.

SCARLET FEVER IN AUGUSTA, ME. — There have of late been a number of cases of scarlet fever in Augusta, which has led to the enforcement of precautionary measures, with good results.

NO SMALL-POX IN LYNN. — A case of suspected small-pox recently reported from Lynn, Mass., has proved to be chicken-pox.

BEQUEST TO A HOSPITAL. — By the will of the late Miss Lydia M. Palmer, the Cambridge Hospital receives $2,000.

NEW YORK.

TANKERD, THE WIFE MURDERER. — In view of a preliminary report from Drs. Charles L. Dana and C. H. C. Steinsieck, who were appointed to examine into the man's sanity, Governor Roosevelt has granted a respite until July 16th next to Tankerd, the convicted wife murderer. The physicians' report states that while Tankerd was undoubtedly sane at the time of his crime and the verdict was just, he is now demented, and ought not, in their opinion, to be sent to the chair. They believe that in six months' time he will be either permanently and hopelessly demented or restored to about his ordinary health, more likely the former.

VALUE OF THE LIFE OF A CHILD. — Abraham Graham, of Jersey City, on January 9th obtained a verdict of $2,000 for the death of his four-year-old boy, who was killed by a trolley car in 1896. This was the fourth trial of the case. In each of the three previous trials the jury gave the father $5,000, but the Court of Errors and Appeals set the judgment aside as excessive. Justice Gammere, who read the opinion when the verdict was set aside the second time, caused a considerable amount of comment by the statement that the life of a child from a legal or money point of view was not worth a dollar.

COLUMBIA UNIVERSITY. — At the first monthly meeting in the new year of the Board of Trustees of Columbia University, held January 8th, Dr. Ellsworth Eliot, Jr., was appointed clinical lecturer on surgery, and Dr. H. E. Hale, assistant demonstrator of anatomy in the Medical Department. At the meeting the announcement was made that John D. Rockefeller had presented $100,000 to the University for the endowment of a chair of psychology.

MEDICAL ASSOCIATION, CITY OF NEW YORK. — At the annual meeting of the Medical Association of the Greater City of New York, held January 8th, the following officers were elected: President, Dr. R. F. Weir; Vice-President, Dr. William McCollom; Recording Secretary, Dr. P. B. Porter; Corresponding and Statistical Secretary, Dr. F. C. Raynor; Treasurer, Dr. A. D. Ruggles. At this meeting Dr. L. Grant Baldwin, of Brooklyn, read the report of a very rare case of properitoneal (interstitial) hernia in a female.

BEQUEST. — The late Dorman B. Eaton, in addition to bequeathing $100,000 each to Harvard and Columbia Universities, left a large amount to societies and charitable institutions. Among the latter bequests were $10,000 to the New York Skin and Cancer Hospital, and $1,000 to the Burnham Industrial Farm.

APPOINTMENTS. — The Governor has appointed Dr. George Elmer Gorham, of Albany, a manager of the Craig Colony for Epileptics, and Dr. Ernest H. Schwindt, of White Plains, a manager of the New York State Reformatory for Women at Bedford.

ST. JOHN'S HOSPITAL. — The new St. John's Hospital in Long Island City, Borough of Queens, was opened January 7th. The building, which cost about $130,000, is four stories high and will accommodate 200 patients.

PHILADELPHIA.

PREVENTION OF TUBERCULOSIS. — On January 10th the Philadelphia County Medical Society and the Pennsylvania Society for the Prevention of Tuberculosis held a joint meeting. Dr. S. Solis-Cohen presided, and introduced the following speakers: Dr. L. F. Flick, "Plans of the Pennsylvania Society for the Prevention of Tuberculosis"; Dr. J. C. Wilson, "The Necessity of Hospital Care of the Consumptive Poor"; Hon. W. N. Ashman, "Work at Present being done through Private Charity in the Treatment of Consumption"; Dr. Howard S. Anders, "The Necessity for State Aid in the Treatment of Consumption among the Poor"; Rev. Chas. A. Dickey, "The Cost of Maintenance and Management of Hospitals and Sanitaria for Treatment of Consumption"; Dr. Guy Hinsdale, "Localities Suitable for the Treatment of Consumption in Sanitaria throughout Pennsylvania": Dr. E. O. Otis (of Boston), "The Necessity for City Hospitals for the Treatment of Advanced Cases of Consumption among the Poor." After the reading of these papers the subject was discussed by members of the Societies and guests. Dr. J. M. Da Costa in opening the discussion showed that the State must take the matter up if anything is to be accomplished. All that individuals can do is, after all, but a drop of relief in an ocean of woe. The discoveries of Koch have, as a matter of fact, added to the hardship of the individual consumptive. Proved to be a source of danger it becomes the duty of the community to come to his relief and the medical profession should urge this upon the State. Addresses were made by Mayor Wm. H. Lambert, formerly President of the Philadelphia Hospital; Dr. J. Edward Stubbert,

of the Loomis Sanitarium at Liberty, N. Y., and Mr. Wm. B. Hackenberg, of the Jewish Hospital in Philadelphia. Dr. S. Solis-Cohen showed that consumption is to be ranked among the preventable diseases; that the means to prevent it are in the improvement of vital resistance by open air, sunlight, good food, proper alternation of rest and exercise, also by the avoidance of infection by proper care of sputum and by certain measures of disinfection of a public nature. Education of the community regarding these methods is necessary. Massachusetts has taken the lead in the erection of a State hospital for tuberculous patients and it is confidently hoped that other States will soon follow her example.

COLLEGE OF PHYSICIANS. — At the last meeting of the College of Physicians of Philadelphia, Dr. W. W. Keen was elected president, and Dr. Horatio C. Wood, vice-president. Dr. Keen has announced his gift of $5,000 toward the endowment of the library of the College. Mr. Chas. C. Harrison, Provost of the University of Pennsylvania, has subscribed $1,000, and the subscriptions to this fund have reached $30,000. It is generally believed that it was Mr. Harrison who made the Christmas gift to the University of the sum of $250,000 towards the endowment of that institution. The donor's name has not officially been made public. This is the second gift of similar amount received by the University within a few weeks.

THE MEDICAL CLUB. — The Medical Club of Philadelphia has elected the following officers for 1900: President, Dr. James M. Anders; Vice-Presidents, Dr. H. Augustus Wilson and Dr. William L. Rodman; Secretary, Dr. Guy Hinsdale; Treasurer, Dr. F. Savary Pearce. The Club has 290 members.

Miscellany.

STATE CONTROL OF THE INSANE.

THE State Board of Insanity has made a special report to the Legislature recommending State care for the insane of Massachusetts. The text of the recommendations is as follows:

(1) Such legislation as will provide that all insane persons who are now or who may hereafter become public charges shall be supported at the expense of the Commonwealth on and after January 1, 1904. This would involve the transfer from city and town account to that of the State of the cost of maintenance at the same rate of some 5,607 persons.

(2) That all such insane poor shall be committed according to the laws for the commitment of the insane to the custody and control of the authorities of the Commonwealth as soon after January 1, 1904, and in such manner, as may be deemed advisable by the State Board of Insanity.

(3) That all such insane poor shall be cared for in buildings which shall be owned or controlled by the Commonwealth. This would require additional provision. (*a*) For about 500 patients who are inmates of the Boston Insane Hospital; (*b*) for about 900 insane persons who are now cared for in city and town almshouses and private families in care of overseers of the poor.

(4) Such legislation as may be necessary to acquire from the State the land, buildings and equipment in use by the Boston Insane Hospital.

(5) That a colony for the chronic insane should be established according to the general plan outlined in this report.

(6) That the Legislature appropriate a sum not exceeding $25,000, to be expended under the direction of the State Board of Insanity, for the purchase of not less than 2,000 acres of land for such colony.

(7) That the Legislature appropriate a sum not exceeding $50,000, to be expended under the direction of a board of trustees, for the proper organization of such a colony, and toward the construction of buildings and the procuring of other equipment necessary for that purpose.

The propositions submitted to us have been considered in relation to a general plan of progressive development, which, in our judgment, better solves the problem than the erection of new hospitals for the specific purposes suggested.

The system recommended is comprehensive and would take some time and the gradual expenditure of money to complete; and, if perfected, will result in a thorough separation of acute from chronic cases, and, we believe, in the best care of both.

The report is signed by George F. Jelly, Herbert R. Howard, Charles R. Codman, Edward S. Bradford and Francis B. Gardner.

EXAMINATION FOR ASSISTANT SURGEONS IN THE UNITED STATES MARINE-HOSPITAL SERVICE.

A BOARD of officers will be convened at the Service Building, 378 Washington Street, New York City, Wednesday, February 7, 1900, for the purpose of examining candidates for admission to the grade of assistant surgeon in the United States Marine-Hospital Service. Candidates must be between twenty-one and thirty years of age, graduates of a respectable medical college, and must furnish testimonials from respectable persons as to character. The following is the usual order of the examination: (1) Physical; (2) written; (3) oral; (4) clinical. In addition to the physical examination, candidates are required to certify that they believe themselves to be free from any ailment which would disqualify them for service in any climate. The examinations are chiefly in writing, and they begin with a short autobiography of the candidate. The remainder of the written exercise consists in examination on the various branches of medicine, surgery and hygiene. The oral examination includes subjects of preliminary education, history, literature and natural sciences. The clinical examination is conducted at a hospital, and when practicable, candidates are required to perform surgical operations on a cadaver. Successful candidates will be numbered according to their attainments on examination, and will be commissioned in the same order, as vacancies occur. After five years' service, assistant surgeons are entitled to examinations for promotion to the grade of passed assistant surgeon. Promotion to the grade of surgeon is made according to seniority, and after due examination, as vacancies occur in that grade.

Assistant surgeons receive sixteen hundred dollars, passed assistant surgeons two thousand dollars, and surgeons twenty-five hundred dollars a year. When quarters are not provided, commutation at the rate of thirty, forty or fifty dollars a month, according to

grade, is allowed. All grades above that of assistant surgeon receive longevity pay, ten per centum in addition to the regular salary for every five years' service up to forty per centum after twenty years' service. The tenure of office is permanent. Officers travelling under orders are allowed actual expenses. For further information, or for invitation to appear before the Board of Examiners, address Supervising Surgeon-General, United States Marine-Hospital Service, Washington, D. C.

COMPULSORY VACCINATION IN JAPAN.

WHILE in England and America, according to the *Indian Lancet*, the utility of vaccination is still doubted, and the right of public enforcement of it disputed by numerous fanatics, we find that in little Japan, the youngest of civilized nations, not only is vaccination compulsory, but revaccination at stated periods is rigidly enforced. By an act of parliament passed in 1896, and at once signed by the Mikado, revaccination at periods of five years was made compulsory upon every Japanese, whatever his or her station in life. Vaccination is done with lymph from calves only, which is procured from vaccine establishments owned and controlled by the government, and which is distributed gratis. Any attempt to evade revaccination at the stated periods is made a serious offence, and is treated as a grave dereliction against public health. The result is that small-pox, once the curse of the islands constituting the realm of Japan, is now all but unknown. Similar results are reported from every country where vaccination is made compulsory and rigidly enforced. Fortunately for Japan, the era of pseudo-science has not yet reached its shores; we fear however that the time may come when the same endless and useless discussions will prevail there that at present mark so much of our own and especially England's legislation in matters of public health. We trust that day may be long deferred.

INFLUENZA IN LONDON.

THERE has, according to the *British Medical Journal*, been a great increase in the number of cases of influenza in London during the last few weeks, and practitioners in many quarters of the town are extremely busily engaged. The returns of the registrar-general for last week reflect this prevalence of the disease by a serious increase in the number of deaths from influenza in London. The deaths directly attributed to this disease, which had been 38 and 69 in the two preceding weeks, further rose to 193 during the week ending Saturday last, December 30, 1899. Of these 193 fatal cases only 24 were of persons under forty years of age, while 63 were of persons aged between forty and sixty, and 96 were of persons aged above sixty years, of which 30 were of persons aged upwards of eighty years. The deaths referred to diseases of the respiratory organs also showed a marked further increase, and numbered no fewer than 1,172, being more than double the average. The information at disposal is not sufficient to show to what extent influenza is prevailing in other parts of the country, but we hear of wide prevalence, apparently in a rather mild form, in East Anglia.

METEOROLOGICAL RECORD

For the week ending January 6th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Date.	Barometer	Thermometer.			Relative humidity.		Direction of wind.		Velocity of wind.		We'th'r. *		Rainfall in inches.

Melrose	14,721	4	—	—	—	—	—	—

Deaths reported 1,830; under five years of age 504; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping-cough, erysipelas and fevers) 190, acute lung diseases 355, consumption 175, diphtheria and croup 81, typhoid fever 33, scarlet fever 22, diarrheal diseases 6, measles and whooping-cough 7 each, erysipelas 5.

From diarrheal diseases Baltimore and Pittsburg 3 each, Philadelphia, Boston, Cincinnati and Washington 2 each, Providence and Charleston 1 each. From measles Providence 5, Philadel-

phia 2, Baltimore and Chelsea 1 each. From whooping-cough Pittsburg 4, Boston, Providence and New Bedford 1 each. From erysipelas Philadelphia and Worcester 2 each, Providence 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,404,408, for the week ending December 30th, the death-rate was 30.6. Deaths reported 6,700: acute diseases of the respiratory organs (London) 1,172, measles 164, diphtheria 122, whooping-cough 102, fever 52, scarlet fever 37, diarrhea 37, small-pox (Hull) 10.

The death-rates ranged from 17.6 in Huddersfield to 49.7 in Plymouth: Birmingham 25.7, Bradford 22.1, Cardiff 20.2, Gateshead 25.9, Leeds 22.3, Liverpool 36.9, London 35.2, Manchester 22.9, Newcastle-on-Tyne 28.3, Nottingham 34.9, Portsmouth 42 1, Sheffield 25.0, Swansea 27.6.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 13, 1900.

R. W. PLUMMER, assistant surgeon, detached from the "New Orleans" and ordered to the "Petrel" and also to the Cavite Naval Station.

D. G. BERRE, assistant surgeon, detached from the "Bennington" and ordered to the "Petrel."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING JANUARY 11, 1900.

AUSTIN, H. W., surgeon. To report at Washington, D. C., for special temporary duty. January 6, 1900. To rejoin station at Philadelphia, Pa. January 11, 1900.

WILLIAMS, L. L., surgeon. Granted leave of absence for ten days. January 11, 1900.

VAUGHAN, G. T., passed assistant surgeon. Detailed to represent the Service at the meeting of the National Pure Food and Drug Congress at Washington, D. C., March 7, 1900. January 11, 1900.

GEDDINGS, H. D., passed assistant surgeon. Detailed to represent the Service at the meeting of the National Pure Food and Drug Congress at Washington, D. C., March 7, 1900. January 11, 1900.

ROSENAU, M. J., passed assistant surgeon. Detailed as delegate to the thirteenth session of the International Congress of Medicine to be held in Paris, France, August 2-9, 1900. January 10, 1900. Detailed to represent the Service at the meeting of the National Pure Food and Drug Congress at Washington, D. C , March 7, 1900. January 11, 1899.

PARKER, H. B., assistant surgeon. Granted leave of absence for thirty days. January 8, 1900.

FRICKS, L. D., assistant surgeon. Detailed to represent the Service at the meeting of the National Pure Food and Drug Congress at Washington, D. C., March 7, 1900. January 11, 1900.

BILLINGS, W. C., assistant surgeon. Detailed to represent the Service at the meeting of the National Pure Food and Drug Congress at Washington, D. C , March 7, 1900. January 11, 1900.

RODMAN, J. C., acting assistant surgeon. Granted leave of absence for four days. January 11, 1900.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday, January 22d, at 8 o'clock.

Dr. Philip C. Knapp will speak briefly on "The Problem of Boston's Insane."

Dr. Henry C. Baldwin will give "A Report of the Work of the Boston Insane Hospital Trustees and Plans for the Development of the Hospital."

ARTHUR K. STONE, M.D., *Secretary*, 637 Boylston Street.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The Section for Obstetrics and Diseases of Women will meet at 19 Boylston Place, Wednesday, January 24, 1900, at 8 P. M.

Papers: Dr. Agnes C. Vietor, "The Question of Supernumerary Fallopian Tubes, with Specimens of Fallopian Tubes with Supernumerary Ostia."

Dr. Charles H. Winn: "Bicornate Uterus with Twin Pregnancy; Abortion from one Horn."

Dr. E. L. Twombly: A Case of Pernicious Vomiting of Pregnancy."

R. A. KINGMAN, M.D., *Chairman*.
C. H. HARE, M.D., *Secretary*.

NEW YORK STATE MEDICAL ASSOCIATION, FIFTH DISTRICT BRANCH. — The sixteenth annual meeting of the Fifth District Branch of the Association will be held in Brooklyn on Tuesday, May 22, 1900. It is proposed to choose diabetes as the topic for discussion. Fellows who are particularly interested in this topic and have any clinical data to present, or theories to offer, will kindly correspond with the undersigned.

J. C. BIERWIRTH, M.D., *President*,
E. H. SQUIBB, M.D., *Secretary*,
P. O. Box 760, Brooklyn.

RECENT DEATHS.

MILTON WILDER HALL, M.D., M.M.S.S., died in Roxbury, January 9, 1900, aged fifty-one years.

JOHN S. COOK, M.D., of Hackettstown, N. J., died on January 1st, in his seventy-fourth year. He was born at Easton, Pa., and was graduated from Union College in 1847 and from the Medical Department of the University of Pennsylvania in 1850. He was elected president of the New Jersey State Medical Society in 1879.

F. H. GEHRING, M.D., a prominent physician at Chateaugay Lake, died recently at Malone, N. Y., from septicemia contracted in performing a surgical operation.

JOSEPH E. ARROWSMITH, M.D., of Keyport, N. J., died January 3d, at the age of seventy-seven years. He was a graduate of the Medical Department of the University of the City of New York, and began practice at Keyport in 1844.

BOOKS AND PAMPHLETS RECEIVED.

A Contribution to the Etiology of Pompholyx. By Martin F. Engman, M.D. Reprint. 1899.

The Tonsils as Portals of Infections. By Emil Mayer, M.D., New York City. Reprint. 1899.

A Review of the History and Literature of Appendicitis. By George M. Edebohls, A.M., M.D., New York. Reprint. 1899.

Disfigurements of Nose and Mouth and their Surgical Treatment. By John B. Roberts, M.D., Philadelphia. Reprint. 1899.

Report of the Trustees of the Rhode Island Hospital, presented to the Corporation at its Thirty-sixth Annual Meeting, November 8, 1899.

Transactions of the American Otological Society, Thirty-second Annual Meeting. Vol. VII, Part II. Published by the Society. 1899.

A RHODE ISLAND PHILOSOPHER (ELISHA BARTLETT).[1]

BY WILLIAM OSLER, M.D.,
Professor of Medicine, Johns Hopkins University, Baltimore, Md.

(Concluded from No. 3, p. 53.)

III.

Bartlett began his career as a medical writer with the *Monthly Journal of Medical Literature and American Medical Students' Gazette*, only three numbers of which were issued. He says in the introductory address, dated October 15, 1831, that there are plenty of practical journals of high character and extensive circulation, but he wishes to see one devoted to "medical history, medical literature, accounts of medical institutions and hospitals, medical biography, including sketches of the character, lives and writings of the chief masters of our art, and of all such as have in any way influenced its destinies and left the deep traces of their labors on its history. . . . To the medical student and the young practitioner, to all those who aspire to any higher acquisitions than the knowledge that calomel purges and salivates, and that tartarized antimony occasions vomiting, who are not willing to rest supinely satisfied in a routine familiarity with doses and symptoms — a familiarity which practice and habit render in the end almost mechanical — we cannot but think these matters must be interesting." And he adds: "The devotion of an occasional hour to such pursuits must have a tendency to enlarge and liberalize the mind. It will help to keep alive and stimulate in the young medical scholar the sometimes flagging energies of study. By calling his attention and directing his desires to high standards of acquisition and excellence, it will urge him on towards their attainment. Delightful and fascinating, in many respects, as the study of his profession may be to him, there are many hours which must be occupied with mental and bodily drudgery. He must make what to others would be loathsomeness pleasure to himself. Amid the wear and tear, the toil and fatigue of such pursuits, he needs at times some intellectual recreation and stimulus, and where can he find one pleasanter or more appropriate than in surveying the career, and studying the characters, of those who have trodden before him the same laborious path, and who have followed it on to its high and bright consummation? If our profession ever vindicates its legitimate claim to the appellation of liberal, it must be cultivated with some other than the single aim of obtaining patients for the sole purpose of getting for services rendered an equivalent in fees."

In the first number there is a statement that on a future occasion the *Journal* will give a "detailed consideration of the character of the old physician of Cos — the venerable father of physic, and of the reform which he effected in medical science," a promise which was not fulfilled to the profession for many years, as Bartlett's well-known lecture on Hippocrates, the last, indeed, of his professional writings, was not issued until 1852. The literature of science, its philosophy, its history, the history of the lives and labors of the founders and cultivators — these he believed it important for the student to cultivate.

[1] An address delivered before the Rhode Island State Medical Society, December 7, 1899.

Among the articles in these three numbers there are some of special merit. One signed S. N., "On the Claims of Medicine to the Character of Certainty," may have suggested to Bartlett his well-known essay, "On the Degree of Certainty in Medicine." The enterprise was not a success, and as Bartlett had said in his introductory address, "of all *weakly* things we most heartily pity weakly periodicals," he had the good sense after three numbers had been issued to give up a publication which the profession did not sustain.

In July, 1832, he became associated with A. L. Pierson and J. B. Flint in a much more pretentious and important journal, the *Medical Magazine*, a monthly publication which continued for three years. It was a very well conducted periodical, with excellent original articles and strongly written editorials. John D. Fisher's original paper on the cephalic brain murmur occurs in Volume II, and in the same one is an excellent paper by E. Hale, Jr., on the typhoid fever of this climate, which is of special interest as containing very accurate statements of the differences between the common New England autumnal fever and the typhus as described by Armstrong and Smith. There are also reports of three autopsies giving an account of ulceration in the small intestine, among the first to be published in this country. There are in addition numerous well-written critical reviews. Among the latter is one of the most virulent productions of that most virulent man, Dr. Charles Caldwell. It is entitled "Medical Language of Literature." I have heard it said in Philadelphia that Dr. Samuel Jackson never forgave the bitterness of the attack in it upon his "Principles of Medicine."

In Volume III there was the interesting announcement that a dollar a page would be paid for all original communications.

In 1831 appeared a little work entitled, "Sketches of the Character and Writings of Eminent Living Surgeons and Physicians of Paris," translated from the French of J. L. H. Peisse. Of the nine lives, those of Dupuytren and Broussais are still of interest to us, and I know of no work in English from which one can get a better insight into the history of medicine in Paris in the early part of this century. One little sentence in the translator's preface is worth quoting: "After making all reasonable allowance for natural tact or talent, and for the facilities and advantages of instruction to be had in extensive medical establishments, it will be found that *study*, intense, untiring, unremitted *study*, is the only foundation of professional worth and distinction."

A great stimulus had been given to the study of phrenology by the visit of Spurzheim to this country. He gave a course of six lectures on the anatomy of the brain and spinal cord at one of the apartments of the Medical College in September of that year, and subsequently a popular course of lectures on phrenology. In 1832 he died in Boston of typhus fever. His brain, it is stated, was in the possession of the Boston Phrenological Society, before which, in January, 1838, Bartlett gave an interesting address on scientific phrenology.

In 1839 Bartlett edited "Paley's Natural Theology," that delightful book, dear especially to those of us who were trained in religious colleges. To some of us at least the freshness of the natural theology, which in Paley's hands was really a delightful commentary on anatomy and physiology, was a happy change from artificial

theology, or even from the "Horæ Paulinæ" of the same author.

Bartlett's claim to remembrance, so far as his medical writings are concerned, rests mainly on his work on "Fevers" issued in 1842, and subsequent editions in the years 1847, 1852 and 1857. It remains one of the most notable of contributions of American physicians to the subject. Between the time of Bartlett's visit to Paris and 1840, a group of students had studied under Louis, and had returned to this country thoroughly familiar with typhoid fever, the prevalent form in the French capital at that time. In another place[5] I have told in detail how largely through their labors the profession learned to recognize the essential differences between the two prevalent forms of fever, typhoid and typhus. The writings on fever chiefly accessible to American readers at that day were the English works of Fordyce, Armstrong, Southwood Smith and Tweedie, in which, as Bartlett says, "they describe a fever or form of fever (that is typhus) rarely met with in this country," and the writings did not actually represent the state of our knowledge upon the subject. Indeed for a number of years later a chaotic condition of mind prevailed among the writers in Great Britain, and it was not until 1849–50 that William Jenner, by a fresh series of accurate observations, brought the British medical opinion into line. As the *British and Foreign Medico-Chirurgical Review*, in a most complimentary notice of Bartlett's work, says, "A history of British fevers such as Louis has furnished to France, or such as given in the volume under discussion, did not exist." Still, even at that date, 1844, the *Review* expressed the ultra-conservative opinion held in England, that the common continued fever, or the low nervous fever of Huxham, was only a mild form of typhus fever. The work is dedicated to his friends, James Jackson, of Boston, and W. W. Gerhard, of Philadelphia; as he states, "a history of two diseases, many points of which they, especially among his own countrymen, have diligently and successfully studied and illustrated."

As to the work itself, the interest to-day rests chiefly with the remarkably accurate picture which is given of typhoid fever — a picture the main outlines of which are as well and firmly drawn as in any work which has appeared since. It is written with great clearness, in logical order, and he shows on every page an accurate acquaintance with the literature of the day, and, as the author of the review already mentioned remarks, a knowledge also of that best of books, the book of nature.

The practical character of Bartlett's mind is indicated by the briefness with which he discusses the favorite topic of the day, namely, the theory of fever. He acknowledged at the outset that the materials for any satisfactory theory of typhoid fever did not exist. He went so far as to claim that the fundamental primary alteration was in the blood, and that the local lesion was really secondary, and he refers to the prevalent theory of fever as "wholly a creation of fancy; the offspring of a false generalization and of a spurious philosophy. What then can its theory be but the shadow of a shade?" This work immediately placed Bartlett in the front rank of American physicians of the day. It had an immense influence on the profession of the country. Among his letters there is an interesting and characteristic one from James Jackson, already referred to in the dedication. Acknowledging the receipt of a copy, he says: "I am now writing to express to you the great satisfaction the book has given me. I think that it entirely answers the end that you proposed. It, in fact, translates to the common reader, in a most clear style and lucid method, the acquisitions which science has made on its subjects within the last few years. Nowhere else can the same comprehensive view of those subjects be found. What may be the conclusions of medical men in regard to essential fevers twenty years hence I would not pretend to say. It is certain their views have changed very much within a shorter period, and if new discoveries are made in ten years to come I doubt not you will be ready to change yours. We must take to-day the truth so far as we know it, and add to it day by day as we learn more."

It is evident from his letters that the success of the work on fevers was a great gratification to Dr. Bartlett. The second edition was issued in 1847, and while the history of typhoid and typhus fever remained much in the same state, with certain additions and developments, the subjects of periodical and yellow fevers were greatly extended. The third edition was issued in 1852. The fourth edition was edited by Bartlett's friend, Alonzo Clark, of New York. The dedication of the second, third and fourth editions was to Dr. John Orne Green, of Lowell, "with whom the early and active part of the writer's life was passed; in a personal friendship which no cloud, for a single moment, ever shadowed or chilled; and in a professional intercourse whose delightful harmony no selfish interest nor personal jealousy ever disturbed."

From every standpoint "Bartlett on Fevers" may be regarded as one of the most successful medical works issued from the medical press, and it richly deserves the comment of the distinguished editor of the fourth edition: "The question may be fairly raised whether any book in our profession illustrates more clearly the beauties of sound reasoning and the advantages of vigorous generalization from carefully selected facts. Certainly no author ever brought to his labor a more high-minded purpose of representing the truth in its simplicity and in its fulness, while few have been possessed of higher gifts to discern, and gracefully to exhibit it."

"An Essay on the Philosophy of Medicine," 1844, a classic in American medical literature, is the most characteristic of Bartlett's works, and the one to which in the future students will turn most often, since it represents one of the most successful attempts to apply the principles of deductive reasoning to medicine, and it moreover illustrates the mental attitude of an acute and thoughtful observer in the middle of the century. The work consists of two parts: in the first science is defined and its canons laid down. Ascertained facts, with their relations to others, obtained by observation or experience, and generalized into laws and principles — this constitutes science. He dwells upon the hurtfulness of theories, and sketches in an interesting manner Newton's position as an observer and as a theorist: "If he (Newton) bowed at any time or in any degree his strong neck to the yoke of hypothesis, it was always with a perfect consciousness of his ability at will to shake it off, as the lion shakes the dew-drop from his mane." He quotes from Sir Humphrey Davy: "When I consider the variety of theories that may be formed on the slender foundation of one

[5] Influence of Louis on American Medicine, Johns Hopkins Hospital Bulletin, August, September, 1897.

or two facts, I am convinced that it is the business of the true philosopher to avoid them altogether."

The five primary propositions with which the second part opens contain the pith of the argument:

Proposition First.— All medical science consists in ascertaining facts, or phenomena, or events; with their relations to other facts, or phenomena, or events; the whole classified and arranged.

Proposition Second.— Each separate class of facts, phenomena, and events, with their relationships, constituting, as far as they go, medical science, can be ascertained in only one way; and that is by observation, or experience. They cannot be deduced, or inferred, from any other class of facts, phenomena, events, or relationships, by any process of induction, or reasoning, independent of observation.

Proposition Third.— An absolute law, or principle, of medical science consists in an absolute and rigorous generalization of some of the facts, phenomena, events, or relationships, by the sum of which the science is constituted. The actual ascertainable laws, or principles, of medical science are, for the most part, not absolute but approximative.

Proposition Fourth.— Medical doctrines, as they are called, are, in most instances, hypothetical explanations, or interpretations, merely, of the ascertained phenomena, and their relationships, of medical science. These explanations consist of certain other assumed and unascertained phenomena and relationships. They do not constitute a legitimate element of medical science. All medical science is absolutely independent of these explanations.

Proposition Fifth.—Diseases, like all other objects of natural history, are susceptible of classification and arrangement. This classification and arrangement will be natural and perfect just in proportion to the number, the importance, and the degree of the similarities and the dissimilarities between the diseases themselves.

Bartlett is the strongest American interpreter of the modern French school of medical observation, which "is characterized by its strict adherence to the study and analysis of morbid phenomena and their relationships; by the accuracy, the positiveness, and the minute detail which it has carried into this study and analysis; and by its rejection as an essential or legitimate element of science of all *a priori* reasoning or speculation. The spirit which animates and guides and moves it is expressed in the saying of Rousseau, 'that all science is in the facts or phenomena of nature and their relationships, and not in the mind of man, which discovers and interprets them.' It is the true *protestant* school of medicine. It either rejects as apocryphal, or holds as of no binding authority, all the traditions of the fathers, unless they are sustained and sanctioned by its own experience."

There are weak points in his arguments, some of which are well pointed out in an able article in the *British and Foreign Medico-Chirurgical Review* (July, 1845), but it is the work of a strong and thoughtful mind, and for a time, at least, it had a powerful influence in the profession. A contemporary writer, S. H. Dickson,[6] speaks of it in the following terms: "It was particularly well-timed, and addressed effectively to the requirements of the profession, at the period of its publication. It breathes a spirit of thoughtful and considerate scepticism, which was then needed to temper the headlong habit of confident polypharmacy prevalent over our country. . . . When addressed, however, by Bartlett, on this side of the Atlantic, and on the other by Forbes, he (the orthodox disciple) stopped to listen and consider. These gifted men spoke with authority; they pleaded impressively, eloquently, wisely. If, in the natural ardor of controversy, they went somewhat too far, let that slight fault be forgiven for the great good they accomplished. Nay, let them be honored for the courage and frankness with which they attacked prevalent error, and risked their popularity and position by assailing modes of practice rendered familiar by custom, and everywhere adopted and trusted to."

In 1848 appeared one of Bartlett's most characteristic works, a little volume of eighty-four pages, entitled, "An Inquiry into the Degree of Certainty of Medicine, and into the Nature and Extent of its Power over Disease." The iconoclastic studies of Louis and certain of the Paris physicians, and the advocacy of expectancy by the leaders of the Vienna school, had between 1830 and 1850 disturbed the profession not a little, and in 1846 appeared an article by Dr. Forbes, in which, as Bartlett said, were drawn "in strong and exaggerated colors the manifold imperfections of medical science and the discouraging uncertainties of medical art." These circumstances had combined to shake and disturb the general confidence in the profession, with the effect that "the hold which medicine has so long had upon the popular mind is loosened; there is a widespread skepticism as to its power of curing diseases, and men are everywhere to be found who deny its pretensions as a science, and reject the benefits and blessings which it proffers them as an art." To Bartlett it appeared high time to speak a clear and earnest word for the science which we study and teach, and for the art which we inculcate and practise, and in this essay he set himself the task of vindicating the claims of medicine to the regard and confidence of mankind. In his endeavor "to show how far and with what measure of certainty and of constancy we are able to control, to mitigate and to remove disease" Bartlett occupied at the outset very advanced ground for that date. We must remember that the general body of the profession had the most implicit confidence in drugs, and polypharmacy was almost as much in vogue as in the seventeenth and eighteenth centuries. The reception of the essay in certain quarters indicates how shocking its tone appeared to some of the staid old conservatives of the day. I came across a review of it in the *Medical Examiner*, November, 1848, from which I give the following extract: "This is a curious production, the like of which we have seldom seen from the pen of any one who had passed the age of a sophomore. What makes it the more remarkable is the circumstance that the writer is a gentleman of education and experience and the author of works which have given him a wide reputation." The force of the rebound sufficiently indicates the intensity with which the attack was felt. Bartlett's position, however, reminds one somewhat of the sermon of the liberal Scotch Presbyterian on "things which cannot be shaken," in which he proceeded at the outset to shake off three-fourths of the cherished beliefs of Evangelical Christianity.

After a preliminary discussion on anatomy and physiology, and on the remarkable rapidity with which these sciences were progressing, he proceeds to speak of the state of pathology and therapeutics as illustrated in the well-known disease pneumonia. Time will not

[6] Gross: American Medical Biography, 1861, p. 750.

permit me to do more than to refer to the result of his analysis of the evidence. He classifies the cases into, first, those which terminate naturally and spontaneously, quite independent of any active medical treatment, a proportion "probably large"; second, a group which will terminate fatally notwithstanding any assistance which art may furnish; they are, as Sir Gilbert Blane said of the worst forms of yellow fever, "determinedly fatal"; and, finally, a third class "not tending necessarily either in one direction or the other," in which the issue depends upon the treatment of the disease. "In theses cases, art, judiciously applied, saves the life of the patient; the issue of the cases, in death or in recovery, is dependent upon the treatment of the disease." Then follows a discussion on the nature and limits of the medical art in the various groups of diseases, and he concludes with a section on the triumphs of preventive medicine.

The initials "A. S." at the end of a review in the *American Journal of the Medical Sciences*, October, 1848, enable us to estimate the impression which the book made upon a kindred spirit. Professor Alfred Stillé, of the University of Pennsylvania (still with us, I am happy to say), wrote, "He has done a good work, a work for which he deserves the respect and gratitude of the medical profession, and of all sound-hearted men, whatever their pursuits, who fight under the banner of truth, and are the sworn foes of all imposture, the determined opponents of all error."

At times and in degrees differing with our temperaments, most of us have bouts of depression, when we feel that the battle has been lost, and that to fight longer is not worth the effort, periods when, amid the weariness, the fever and the fret of daily practice, things have gone against us; we have been misunderstood by patients, our motives have been wrongly interpreted, and smitten perhaps in the house of our friends, the worries of heart to which we doctors are so subject, make us feel bitterly the uncertainties of medicine as a profession, and at times make us despair of its future. In a voice that one may trust Bartlett concludes his inquiry with these memorable words, which I quote, in the hope that they may soothe the heartache of any pessimistic brother: "There is no process which can reckon up the amount of good which the science and art of medicine have conferred upon the human race; there is no moral calculus that can grasp and comprehend the sum of their beneficent operations. Ever since the first dawn of civilization and learning, through

'the dark backward, and abysm of time,'

they have been the true and constant friends of the suffering sons and daughters of men. Through their ministers and disciples, they have cheered the despondings; they have lightened the load of human sorrow; they have dispelled or diminished the gloom of the sick-chamber; they have plucked from the pillow of pain its thorns, and made the hard couch soft with the poppies of delicious rest; they have let in the light of joy upon dark and desolate dwellings; they have rekindled the lamp of hope in the bosom of despair; they have called back the radiance of the lustreless eye and the bloom of the fading cheek; they have sent new vigor through the failing limbs; and, finally, when exhausted in all their other resources, and baffled in their skill — handmaids of philosophy and religion — they have blunted the arrows of death, and rendered less rugged and precipitous the inevitable pathway to the tomb. In the circle of human duties, I do not know of any, short of heroic and perilous daring, or religious martyrdom and self-sacrifice, higher and nobler, than those of the physician. His daily round of labor is crowded with beneficence, and his nightly sleep is broken, that others may have better rest. His whole life is a blessed ministry of consolation and hope."

The last of Bartlett's strictly medical publications was a little monograph on the "History, Diagnosis and Treatment of Edematous Laryngitis," published in Louisville at the time he held the chair of practice at the University, in 1850. It is a carefully prepared monograph, based largely on the studies of Valleix, and to which a fresh interest had been given him by the observations of Dr. Gurdon Buck, of New York, who had cured several cases by directly scarifying the edematous membranes.

IV.

Naturally studious, fond of poetry, history, biography and literature in general, and not for long tied and bound in the chains of general practice, Bartlett had ample opportunities to cultivate his mind. He says in one of his letters to Green (dated Pittsfield, November 1, 1835): "I pass a good deal of my time here quite alone, so that I find myself whiling away the hours in meditation much oftener than when engaged in the more varied and active affairs of business at home. I think that I always leave Pittsfield with the better and purer part of my being somewhat strengthened." Burton concludes his immortal treatise with the advice: "Be not solitary, be not idle," but the true student in some part of his life at least, should know the "fruitful hours of still increase." For many years Bartlett enjoyed a leisure known to-day to few professors of medicine, the fruits of which are manifest in his writings. Among his contemporaries in the profession there were brilliant writers, — Samuel Henry Dickson, Jacob Bigelow, J. K. Mitchell, — but in a style so uniformly high and polished, yet withal so plain, not one of them approached Bartlett. Compare, for example, Samuel Jackson's "Principles of Medicine," written in 1832 with the first edition of the "Fevers" (1842) — the one pompous, involved, obscure; the other clear, direct, simple. For style in his medical writings Bartlett may be called the Watson or the Trousseau of America.

Bartlett was at his best in the occasional address, and, as we have noticed already, this talent was cultivated very early in his career, since we find him giving the Fourth of July oration before his fellow-citizens when he had been scarcely a year in Lowell. All of the lectures and addresses illustrate, as Holmes said, "that easy flow of language, that facility of expression, that florid warmth when occasion offers, which commonly marks the prose of those who are born poets." Among these addresses there are four or five worthy of a permanent place in our literature. Perhaps the most characteristic is one entitled, "The Head and the Heart, or the Relative Importance of Intellectual and Moral Education," which is a stirring plea for a higher tone in social and political morality. In the same clear, ringing accent he speaks in his address on Spurzheim of the dangers of democracy. In a lecture on the "Sense of the Beautiful," delivered in 1843, Bartlett appears as an apostle of culture,

pleading in glowing language for the education of this faculty. One short fragrment I must quote: "Amongst the Hebrews, and in the age of Moses, it was linked to religion; it dwelt amidst the mysteries of Worship and Faith. It brought costly offerings to the costlier altar; it hung the tabernacle with its curtains of fine twined linen, and blue, and purple, and scarlet; and with cherubim of cunning work; it arrayed the high priest of Jehovah in his gorgeous and consecrated garments, and on the mitre of pure gold upon his forehead, it graved, like the engraving of a signet — Holiness to the Lord. At a later day, and amongst a widely different people, it became the handmaid of a refined and luxurious sensuality. It lapped the soul of Greece in a sensual elysium. Its living impersonations were Pericles and Aspasia. It called the mother of love from the froth of the sea, and bound her zone with its cestus; it filled the hills of Arcady with fleet Oreads; it graced with half-naked Naiads the fountains and the rivers. It crowned the Acropolis with the Parthenon, and it embodied its highest conceptions of physical grace and beauty in the Venus and the Apollo. At other periods during the history of our race, it has manifested itself in other forms than these; under other circumstances, aspects and influences, and with other results."

In 1848 he delivered the Fourth of July oration before his old friends in Lowell. At the opening he refers to the fact that twenty years before he had occupied the same position. "It was the dewy morning of my manhood; 'time had not thinned my flowing hair'; life, with its boundless hopes and its golden visions, spread far and fair before me; and cheered by your words of encouragement, and aided by your helping hands,— your associate and co-worker, and in your service; a stranger, but welcomed with frank confidence and trust,— I had just entered upon its arduous and upward pathway."

In 1849 appeared a "Brief Sketch of the Life, Character and Writings of William Charles Wells," the South Carolinian Tory, who subsequently became a distinguished man of science in London, and who was well known for his researches on the phenomena of dew.

One of the last of Bartlett's publications was "A Discourse on the Times, Character and Writings of Hippocrates," delivered as an introductory address before the trustees, faculty and medical class of the College of Physicians and Surgeons, at the opening of the session of 1852–53. The three pictures which he gives of Hippocrates, as a young practitioner in the Isle of Thasos, at the death-bed of Pericles, and as a teacher in the Isle of Cos, are masterpieces worthy of Walter Savage Landor, and I regret that time does not permit me to make quotations. In no words of exaggeration the late George D. Prentice said, "There are but few word pictures in the English language that exceed the grandeur and loveliness of that one called into being by Dr. Bartlett in which he imagines Pericles upon his death-bed with Hippocrates in attendance."

It is remarkable how many physicians write poetry, or what passes as such. I have been told of a period in the history of the Royal College of Physicians of London when every elect (censor), as they were called, had written verses. Some begin young, as did Bartlett; others become attuned in the deep autumnal tone of advancing years, when, as Plato tells us in the *Phaedo*, even Socrates felt a divine impulsion to compose and make verses before quitting the prison house. Those of us who have read the epic of the late distinguished Prof. George B. Wood, of the University of Pennsylvania, entitled "First and Last," published when he was sixty-four, will devoutly hope that professors of medicine, when afflicted with this form of madness, will follow his example and publish their poems anonymously and in another country. Jacob Bigelow, too, when nearly seventy, "darkened sanctities with song" with his American "Rejected Addresses" (Eolopoesis).

Dr. Bartlett had poetical aspirations early in life. In a letter to his sister of December 3, 1826, he speaks of having seen in New York, in the *Garland*, "two fugitive pieces which some months before I had made use of to fill up the corner of a newspaper, but what sense they might have contained had been turned into nonsense, and I blushed for my wandering orphans, notwithstanding they had been so well dressed, and though they had found their way into pretty respectable company. I should have blushed for myself had they been exhibited to the public as my offspring." In another letter of the same period we see how completely he had passed beneath the yoke of Byron.

At the end of December, 1854, Bartlett issued a little volume entitled, "Simple Settings in Verse, for Six Portraits and Pictures from Mr. Dickens's Gallery," the inditing of which had been, as he says, a pleasant occupation which had helped to while away and fill up many a hour which would otherwise have been weary or vacant in his invalid life. I have already spoken of one, "An Allegory," in which are autobiographical details. I cannot do better than to quote the appreciative notice which his friend Oliver Wendell Holmes gave to the little volume. "When, to the friends he had loved, there came a farewell gift, not a last effort of the learning and wisdom they had been taught to expect from him, but a little book with a few songs in it, songs with his whole warm heart in them, they knew that his hour was come, and their tears fell fast as they read the loving thoughts that he had clothed in words of natural beauty and melody. The cluster of evening primroses had opened and the night was close at hand."

Of a warm, affectionate nature,— a manhood fused with female grace,— to judge from the statements of contemporaries and friends, to know Bartlett was to love him. His confrères, John Orne Green and Alonzo Clark, are invariably addressed as "Dear Brother." Among the letters is one of sympathy to Dr. Green, the desire of whose eyes had been taken away at a stroke. In it Bartlett unlocked his heart in a most touching and human appeal to the afflicted soul. It seems almost too sacred to quote, but after listening you will forgive me.

"My Dear Brother: What shall I say to the melancholy allusion, in the close of your letter, to the death of our dear Minerva? What poor words of mine can be of any service to one on whom the hand of the Great Chastener has been so heavily laid? How shall I, whose life has been comparatively so cloudless and serene, come, with the message of solace and encouragement, into the presence of one whose meridian sun has been shrouded in such utter and dreadful eclipse? But why should I not? Am I not a brother and a man? Has not bereavement been a guest in the dwelling of my childhood; has not death been a familiar visitor

amid the scenes of my early friendships and happiness and hopes? And where, too, is the future — for us all — for me, as well as for yourself? We but follow each other through the furnace of affliction, as we follow each other to the grave. Who of us has so hedged in his earthly treasures that the spoiler cannot easily break through the frail enclosure, and rifle him, in a moment, of the choicest and best? The lines of the Christian poet, familiar to me, chiefly, from the lips of a now sainted mother, occur to my memory here:

> 'The spider's most attenuated thread
> Is cord, is cable, to man's tender tie
> On earthly bliss; – it breaks at every breeze.'

We are brothers, then, in all the liabilities and contingencies and uncertainties of the future. Let us be brothers and fellow-helpers, also, in its hopes and its duties. There can be no entire and hopeless wretchedness for the soul of man, except that which arises from its self-inflicted degradation. The sweet sister, the affectionate daughter, the beautiful bride, and the young mother, was taken away in the clear, unclouded morning of her life — taken away, but where? And by whom? The flower was transplanted from an earthly garden — a fair and sunny one, it is true, but from an earthly garden — to be set forever where no worm can feed on its root, where no decay can ever dry up its bloom — in the Paradise of God. By whom? Taken away — by her Father, from a far-off country, where she was only a sojourner or a pilgrim — to her beautiful and eternal home. Take these thoughts into your heart, and they shall lighten up, or drive away, the darkness of the past, and, what is better, they shall again cheer your future with the once familiar forms and faces of Happiness and Hope. How can we know what, even of present good, our indulgent Father may have in store for us? He may have allotted to you many long years, to be filled up first with duty, and, if filled with duty, to be crowned, also, with the cheerful light of social and domestic joy. You may say, perhaps, that this is all very well for me to say, but that I know nothing about it. But I do know something of the mutability of all earthly things. This uncertainty has long been to me a daily theme of meditation; so I am not wholly a stranger. But I have found an antidote to the gloom and sadness which would otherwise occasion in remembering that all things are in the hands of a Wise Disposer, and the surest way to please Him, as well as to secure our own present as well as future peace, is to submit to His dispensations and to follow on in the course of active and cheerful duty to Him, to our fellows and to ourselves."

While at Louisville some obscure nervous trouble, the nature of which I have not been able to ascertain, attacked Dr. Bartlett. Against it in New York he fought bravely but in vain, and after the session of 1853–54 retired to Smithfield, his native place. The prolonged illness terminated in paralysis, but fortunately, did not impair his mental faculties in the slightest. He died on the 19th of July, 1855.

From the many eulogies which appeared after Bartlett's death, I select a portion of one written by his dearest friend, Alonzo Clark, as the preface to the fourth edition of the "Fevers." "Sixteen months ago, he closed his brilliant professional career, after years of growing bodily weakness and pain; his mind not dimmed by his physical infirmities, but bright and comprehensive, glowing with the memories of the past, and the visions of the future. He died too soon for the profession he adorned. The clock had hardly marked twelve at noon, on the dial plate of life, when its pendulum strokes grew faint and gradually fainter to the ear; and now, at length, when all is still, the hand that notes the hours points sadly upward, to indicate how much of daytime still remained to reap the harvest of affection and honor in those fields from which he had already garnered up so many golden sheaves. He died, alas! too soon. The whole profession are his mourners; for conspicuous as he had become by his medical writings and his extended professional labors, his acknowledged worthiness, his innate gentleness and modesty disarmed envy. He left no enemies. His mind and purpose were pure, almost beyond example. His high mental endowments were controlled and directed by a considerate judgment and an earnest, benevolent heart; and as the laws of refraction, wrought out into mathematical formulæ, enable the lapidary to construct the facets which open the fountains of the many-colored diamond, so for him, cultivation and elegant taste had brought out the varied and winning native lights of his rich intellectual, moral and social nature."

In translating the "Lives of Eminent French Physicians," Bartlett said he had a two-fold object: "First, the delineation of distinguished professional character and attainment, and secondly, by the influence of such high examples to awaken in the younger members of the medical body a more devoted and worthy emulation of the great masters of our art." In this spirit I appear before you to-day, glad to tell over the story of your countryman — the story of "a life in civic action warm," one that all "the muses deck't with gifts of grace," a distinguished teacher, an author of widespread influence and distinction, a serene philosopher, but above all a man in whom you may recognize, even from the brief and imperfect sketch which I have given,

> "A likeness to the wise below,
> A kinship with the great of old."

SIXTEEN YEARS' EXPERIENCE IN FOOD AND DRUG INSPECTION.[1]

BY SAMUEL W. ABBOTT, M.D., BOSTON,
Secretary State Board of Health.

THE following brief sketch relates to the work of the State Board of Health of Massachusetts in the line of food and drug inspection for the period beginning with 1883 and extending to the present time.

Several investigations had been made in the early history of the Board relative to this subject,[2] and it was found that a considerable amount of adulteration existed in the various articles used for human food.

A prize of $1,000 had been offered by the National Board of Trade in 1880 for the best essay upon the subject, to be accompanied with a draft of an act, as a guide to the necessary legislation. The prize was awarded to Prof. G. W. Wigner, Secretary of the British Society of Public Analysts, and upon his draft of a bill, the law of Massachusetts was passed substantially as it now stands. Several amendments have been made from time to time as experience has dictated.

[1] Read at the annual meeting of the American Public Health Association, November, 1899.
[2] See reports of 1872, 1873, 1879 and 1882.

For the first year under the operation of this law the time was mainly spent in inspection of the food actually found as offered for sale in the State, an appropriation of $3,000 for this purpose having been made.

The second year a severe attack was made upon the law by persons who feared that its operation might prove a hindrance to the dishonest speculator in impure food, and the war was carried into the Legislature. But the honest farmer and grocer and druggist came to the rescue, and the result was an additional appropriation, making $5,000 for the second year's work. In the third year the same tactics were again tried. Inflammatory circulars were issued by persons desirous of breaking down the bars and appealing to the fears of timid milkmen and druggists. The result was the same as before, and the appropriation was doubled, making it $10,000 instead of $5,000. For the past four years the appropriation has been $11,500 annually. With this amount it is possible to conduct a fair amount of inspection through the whole State. Under the provisions of the law, three-fifths of the annual appropriation must be spent in enforcing the laws relating to milk and milk products.

In addition to the general act of 1882 (which is much the same as that enacted in other States), we have several laws relating to special articles of food, and particularly in regard to milk. Under these acts the Board has collected and examined in these sixteen years of work about 110,000 specimens or samples of food and drugs, and has conducted about 1,400 prosecutions against offenders. The amount of fines turned into the treasuries of towns and counties has been $83,000, the total amount expended in carrying out the provisions of the law having been about $160,000 in the sixteen years. The details of the work are to be found in the annual reports of the Board and are summarized in the following table:

Of the whole number of samples examined, and included in the foregoing summary, 51,198 were samples of milk, 36,524 were other kinds of food, and 9,868 were drugs, patent medicines, cosmetics and other articles of similar character.

One of the results of the early investigations of the Board was the proof that the adulterations in common use were mainly of a commercial and not of a harmful character. The staple articles of food, including the principal cereals, with sugar, and very many other useful and nutritious kinds of food, are almost never adulterated, so that the actual ratio of adulteration is limited to a minor portion of the food supply. The public is often led to believe the contrary by means of alarming and sensational statements in the newspapers, such as have recently appeared, but actual inspection does not confirm these statements. For example, a recent statement circulated throughout the country affirmed that wheat flour was being largely adulterated, and in many instances by injurious substances. A collection of many samples of flour from different parts of the State was made by the inspectors, the result of which showed, on examination, that only five samples consisted of anything but pure wheat flour, and in these instances the addition consisted of a small quantity of corn meal. The value of a food supply of a State, however, is so great as to warrant a continuous watch over its quality, since the few articles which are liable to adulteration are of sufficient consequence and value to require constant

FOOD AND DRUG INSPECTION, MASSACHUSETTS STATE BOARD OF HEALTH (1883-98).

Summary.	Years.							
	1883.	1884.	1885.	1886.	1887.	1888.	1889.	1890.
Total examinations of food and drugs	1,298	2,644	4,778	4,326	5,420	5,786	5,454	5,985
Total examinations of good quality	720	1,210	2,751	2,649	3,563	4,019	3,716	4,096
Total examinations not conforming to the statutes	578	1,434	2,027	1,677	1,857	1,747	1,738	1,889
Percentage of adulteration	44.5	54.2	42.7	38.7	34.3	30.3	31.9	31.5
Expense of collection, examination and prosecution	$2,931.56	$5,529.60	$8,557.43	$8,025.34	$8,803.62	$8,915.41	$10,356.28	$10,013.04
Expense of collection, examination and prosecution, per sample	2.26	2.09	1.79	1.85	1.62	1.54	1.89	1.67

FOOD AND DRUG INSPECTION (Concluded).

Summary.	Years.								Totals.
	1891.	1892.	1893.	1894.	1895.	1896.	1897.	1898.	
Total examinations of food and drugs	5,294	6,199	6,409	6,874	7,309	8,357	10,680	10,797	97,590
Total examinations of good quality	3,558	4,111	4,410	4,684	4,496	6,133	8,030	8,076	66,222
Total examinations not conforming to the statutes	1,736	2,088	1,999	2,190	2,813	2,224	2,650	2,721	31,368
Percentage of adulteration,	32.8	33.7	31.2	31.9	38.5	26.6	24.8	25.2	32.1
Expense of collection, examination and prosecution	$10,019.41	$11,180.30	$10,454.11	$10,364.64	$11,375.89	$10,921.61	$12,076.43	$11,062.68	$150,587.35
Expense of collection, examination and prosecution, per sample	1.89	1.80	1.63	1.52	1.56	1.23	1.13	1.02	1.54

supervision to prevent the occurrence of fraud. New and ingenious methods of adulteration frequently make their appearance and demand the exercise of watchfulness on the part of the officials charged with the execution of the law.

The actual cost of the food supply of the population may be determined approximately by observation among different classes of people. The Bureau of Labor Statistics of Massachusetts in an article by Prof. W. O. Atwater, Report of 1886, page 323, states the average cost of the daily ration, by observance of very many dietaries of persons of different occupations, at twenty-five cents. This does not include luxuries, but the common forms of animal and vegetable food necessary for the support of life in a healthy condition.

The daily ration of seventy-five millions of people upon this basis would be worth $18,750,000 and the yearly cost $6,843,750,000. If only one-fourth of this amount represents the value of the articles which are liable to adulteration, the comparatively small sum which the different States annually appropriate for the work of careful inspection constitutes a good investment.

The articles most liable to adulteration are milk, butter, spices, coffee, syrups and molasses, cream of tartar, honey, vinegar, jellies and jams, olive oil, and certain kinds of canned goods.

The milk supply of the State is one of the most valuable constituents of its general food supply. An expenditure of two cents each day per capita for milk amounts to an immense yearly sum when reckoned for the whole population.

In addition to the ordinary methods of milk adulteration, the addition of water, and the abstraction of cream, two other questions frequently present themselves in the course of the milk inspection of large cities and towns — the addition of coloring matter and the use of preservatives.

With reference to the propriety of treating the former of these subjects, the addition of coloring matter, as a distinct form of adulteration, in which the motive for its use is usually a fraudulent one, there can be little doubt; and the officials of the Board have been instructed to use every possible means to suppress the practice.

With reference to the use of preservatives in milk, the present statute does not admit of any discretion, since any such addition constitutes "a foreign substance," under the provisions of Public Statutes, Massachusetts, Chapter 57, Section 5, and the later amendments of the same statutes.

The further question, whether additions of such preservatives as boracic acid, borax, bicarbonate of soda, salicylic acid, formaldehyde or other similar substances in such quantities only as may be required to preserve the milk for a period of twenty-four or forty-eight hours, are injurious to the health of the consumer, does not yet appear to have been definitely settled. The subject has recently been discussed with renewed vigor in the British medical and sanitary journals without arriving at conclusions which may be deemed satisfactory.

If the use of such substances for the preservation of milk is to be permitted, it is plain that some definite quantitative limit should be fixed, an excess of which should be deemed a violation of statute.

In 1897 several amendments to the food acts of the State were made, some of greater and some of less importance, all of which had in view the protection of the general consumer and the prevention of special kinds of adulteration.

The following amendment to the general law of 1882 has had a wholesome effect, since it introduced certain provisions which had not hitherto been embraced in any statute.

Section 3, last paragraph of Chapter 344 of the Act of 1897, reads as follows:

Provided, that the provisions of this act shall not apply to mixtures or compounds recognized as ordinary articles or ingredients of articles of food, if every package sold or offered for sale is distinctly labelled as a mixture or compound *with the name and per cent. of each ingredient therein*, and if such mixtures or compounds are not injurious to health.

The important amendment in the foregoing paragraph consists in the italicized words, which require the name and percentage of each ingredient in a mixture or compound to be distinctly placed upon each package.

The articles to which this applies, as found by the operation of the law during the past two years, are principally coffee preparations, or imitations of coffee, containing chicory and cereal products, spices, syrups, molasses, and baking powders. Several complaints have been made and convictions secured under this provision, and have had a decided effect in securing a better condition of the market so far as the proper labelling of compound articles of food is concerned.

This question of the proper labelling of food products is one of considerable importance, as every one who has had occasion to administer food statutes very well knows. Many of the complaints which have been entered in court in the past few years have rested upon the ground of fraudulent or indistinct or insufficient labels.

The regular routine work of the Board in the department of food comprises the collection of articles of food and drugs from all parts of the State by experienced inspectors and their examination by the analysts of the Board, with the preparation of cases for trial in court. In addition to this routine work, the office is also open daily for the reception of such articles as may be brought in for examination. The articles of this character have not been numerous when compared with those which have been collected by the inspectors, but have represented very nearly all classes of food. The examinations of this class have also extended occasionally to articles not mentioned in the law, but are usually embraced very properly in the laws of other countries among the things which it is deemed proper for sanitary boards to examine, such as cooking utensils and articles intended for the conveyance and storage of drinking-water, wall paper and fabrics used for wearing apparel, children's toys, and other articles in common use among the people.

The articles which were brought to the office for examination during the past year, and were not collected by the inspectors, are included in the following list: Articles of food suspected of containing poisons, milk, spices, coffee, cream, molasses, confectionery, butter, maple syrup, flavoring extracts, flour, honey, diabetic flour, hair dyes, cosmetics and other proprietary medicines, whiskey, wine and cider, wax, wall paper and fabrics to be examined for arsenic, cooking utensils and toys.

The essentials necessary for carrying out a system of food and drug inspection are:

(1) A sufficient annual appropriation.

(2) A well-equipped laboratory, comprising the necessary apparatus and reagents for chemical analysis, and especially for the examination of milk; microscopes for the examination of spices, coffee and other articles requiring ocular inspection. A small weighing-room and a room for polarizing apparatus. It is also convenient to add a closet for photographing purposes, in order to place on permanent record some of the important forms of adulteration.

The officials necessary for the work are:

(1) A general director, who should be made responsible for the careful and thorough execution of the work of the department. All cases intended for prosecution should first be referred to him for consideration, and he should consider all cases of doubtful or disputed analysis. This person may or may not be connected with a health board. In some of the States, as in Ohio and Connecticut, the work is entrusted by law to a single independent commission.

(2) An experienced food chemist or analyst. I use the term analyst as preferable since much of the work of food inspection belongs to the domain of physics or of microscopy rather than to that of chemistry. This official should not only be an expert in his profession, but should have the qualities requisite for testifying with clearness and decision when upon the stand in court, in such terms as an ordinary jury or municipal judge may clearly comprehend. The chemist should receive the samples by number only, all labels, marks, brands or other indications of their sources or places of sale being removed before they are submitted to him.

(3) The collector of samples. The duties of this official are necessarily complex. Primarily, he has authority to travel throughout the States visiting the different cities and towns, and to collect by purchase such articles, under proper supervision, as are most liable to adulteration. He should keep a vigilant eye upon the markets with a view to detecting the appearance of new and unexpected forms of fraud and adulteration, and should at once report any such matters to the general director. While in order to be a good collector it is not necessary that he should in any degree usurp the functions of the analyst or chemist, he should, nevertheless, possess the faculty of keen observation such as is essential to a successful detection, that is to say, he should use his senses, those of sight, smell, taste and feeling, since by the employment of these powers in detecting the gross appearances of articles of food, half the work of food inspection is often accomplished before submitting samples to the chemist. He should also be familiar with the laws relating to food and should possess the requisite knowledge and skill to make complaints at court, to examine witnesses, and prosecute cases before district and municipal judges.

The question will naturally be asked, What advantage is gained by the enactment of food laws and their execution, since enactment alone is of little use without enforcement? The real advantage gained cannot be exactly stated by means of figures representing pecuniary gain. The saving consists not so much in actual money returned to the pockets of the consumer, as in an improvement in the quality of the articles purchased, and in the sense of security which is afforded by a well-executed law.

That those States that have no such system of inspection have an inferior food supply (so far as relates to articles liable to adulteration) is susceptible of proof, since occasional inspections made in those States have shown this to be the case.

There can, therefore, be no reasonable doubt that the system is well worthy of adoption in all communities. It is now in force in almost every large city on the continent of Europe as well as in Great Britain, and commends itself for general adoption everywhere, until the day shall come when man will no longer line his own pockets by defrauding his neighbor.

THE VALUE OF X-RAY EXAMINATIONS IN THE LESS FREQUENT DISEASES OF THE CHEST ILLUSTRATED BY THEIR USE IN THOSE CASES WHERE ANEURISM IS PRESENT OR SUSPECTED.

BY FRANCIS H. WILLIAMS, M.D., BOSTON.

(Concluded from No. 3, p. 57.)

A BUNCH OF ENLARGED GLANDS WHICH GAVE OUTLINES ON THE FLUORESCENT SCREEN SUGGESTIVE OF ANEURISM.

Case VI. (Fig. 4.) Mr. C., forty years of age, referred to me by Dr. Farlow for x-ray examination.

X-ray examination. — Appearances which indicate an aneurism of aorta. There is obstruction to expiration; the lungs are dilated to their fullest extent; the diaphragm is low down in the chest, nearly to the costal border, and moves very little in expiration. No pulsation of the outline is noticed. It is not improbable that the appearances are due to a new growth which obstructs the trachea. This patient was seen by me once and only an examination with the fluoroscope was made. I expected to see him again, get history, and take an x-ray photograph, but did not; and with this incomplete examination I inclined to the diagnosis of aneurism rather than to that of a new growth.

Since the above note in the first paragraph was written, I have seen an article by Dr. Classen in the *Albany Medical Annals*, in which he makes an excellent report of the clinical features of the case, and gives a record of the careful autopsy made by Dr. Lartigau. The patient died on May 10, 1899. No aneurism was found, and the portion of the autopsy record relating to the aorta is as follows:

"*Aorta.*—Shows no apparent dilatation at any point. The circumference of the thoracic aorta is 5.5 centimetres; the circumference of the abdominal aorta is five centimetres. The intima is markedly irregular, the irregularity being due to various-sized areas of elevated fatty atheroma. Behind the trachea at a point on a level with the aortic arch, and situated more to the left of the median line, is a bunch of enlarged glands about the size of a small orange. The individual glands vary in size from a pea to those having a diameter of three centimetres. They are firm in consistency, and are on section deeply pigmented in the central portions, less so in the peripheries, which are apparently congested. The central pigmented portions are black. Now and then on the sectioned gland small pinpoint to pin-head-sized, discrete hemorrhages are apparrent. The individual glands are bound together by old firm bands of connective tissue."

This case is chosen to show how some other disease

may give outlines on the fluorescent screen that simulate those produced by an aneurism, and to emphasize the importance of considering other indications besides the outlines themselves. In this patient the history, the absence of pulsation, and obstruction to expiration on both sides were against a small aneurism. In other patients I have observed this incomplete expiration where there was obstruction of the air passage of one or both lungs.

DIAGNOSIS OF AORTIC ANEURISM BY X-RAY EXAMINATION CONFIRMED BY AUTOPSY.

CASE VII.[3] (Fig. 5.) A man forty-five years old was brought to me for examination, from the Out-Patient Department, by Dr. Arnold, on February 18, 1899, with diagnosis of probable aneurism of the innominate artery and possible aneurism of the aorta.

Family history. — Father died of apoplexy at fifty-five years.

Past history. — "Chancroid" thirty years ago. Alcohol in moderation.

Present illness. — One week ago pain and sense of intense pressure in precordium; pain increased by exertion; some cough and expectoration; slight attacks of hoarseness two or three times in the past few days, but not at present.

Physical examination. — Just above inner end of right clavicle is a marked pulsation, being greater than

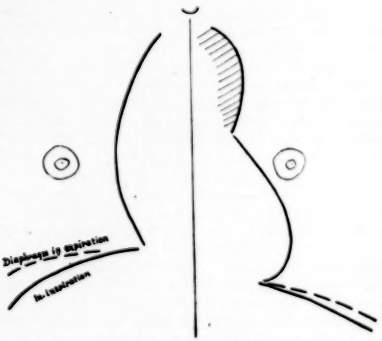

FIG. 4. Case VI. About one-fourth original size.

in corresponding place on left side. At the episternal notch pulsation is greater than normal, felt more distinctly on the right side; there being also a thrust from the right instead of from below upwards. Above the inner end of right clavicle, just outside of the sternomastoid muscle, a thrill is felt. There is a slight but distinct tracheal tug. Left radial pulse delayed. Cardiac apex beat in sixth interspace in mammary line. Over aortic area are systolic and diastolic murmurs transmitted along course of aorta and innominate artery, and heard distinctly over inner end of right clavicle. Systolic murmur is carried to the left subclavian and carotid arteries, but not the diastolic. Slight systolic murmur at apex.

The x-ray examination made February 18th revealed a small aneurism of the descending portion of the aortic arch, which gave no physical signs even after the x-ray examination.

On February 23d, the patient was found on the street unconscious, was brought into my service at the hospital, and a few moments later died. No cause of death was discovered by Dr. Pearce at the post-mortem, but the autopsy showed a small aneurism of the descending portion of the aortic arch corresponding to the outline drawn at the x-ray examination, likewise an aneurismal dilatation of the innominate artery.

It will be seen by comparing the x-ray lines with the dotted lines, which represent the outlines found by percussion, that we failed to recognize any dulness over the site of the aneurism, and even after I had *seen* its outline on the fluorescent screen we could not detect it by percussion. Further, by following the dotted line which indicates the left border of the heart as found by percussion, we see that it is incorrect, when compared

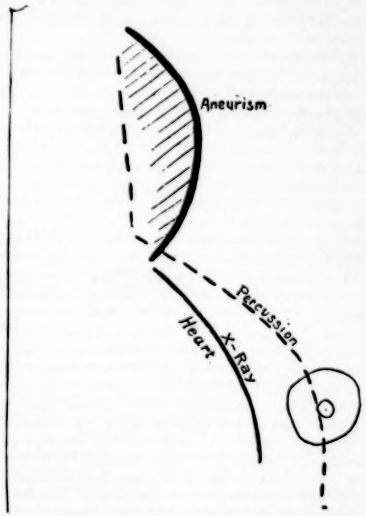

FIG. 5. Case VII. One-third original size.

with the same border as determined by the fluoroscope and at the autopsy. In cardiac disease I have frequently demonstrated a discrepancy between the position of the borders of the heart as suggested by percussion and as determined by means of the fluorescent screen.

A further point of interest in this patient is that the lungs were found to be normal both by the x-ray and post-mortem examinations.

ANEURISM UNSUSPECTED BY PHYSICAL EXAMINATION.

CASE VIII. J. McC., a man, forty years old, referred to me from the Out-Patient Department by Dr. Arnold, illustrates some cases of the class in which aneurism could not be made out on physical examination, and was discovered in the x-ray examination made to determine the size of the heart.

[3] This case was cited by me in the Boston Medical and Surgical Journal, May 18, 1899.

History.— Syphilis eleven years ago; rheumatism six years ago; alcohol habitually.

Present illness.— Marked dyspnea on exertion and at times vertigo; very nervous and sleeps poorly; pain at times in the left shoulder and breast; visible pulsation of all large arteries; capillary pulse; heart dulness begins below third rib and extends two centimetres to right of sternum; apex in sixth interspace, three centimetres outside nipple line; double murmurs over aortic area; similar murmurs at apex, which are transmitted toward axilla; diastolic murmur heard over epigastrium, and systolic over large areas in back; diffuse visible pulsation over cardiac area.

X-ray examination revealed with unusual clearness a small aneurism of the descending arch of the aorta, and its pulsations were easily seen. Two examinations were made, with an interval of three weeks between them, and the outline of the aneurism was readily observed; most clearly when the fluorescent

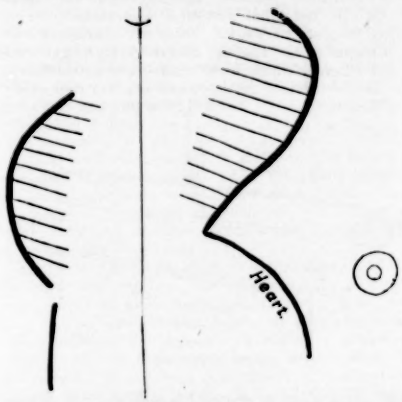

FIG. 6. Case IX.

screen was placed over the upper part of the left scapula. Dr. Bartol kindly brought the patient to me on April 15 and June 3, 1899. We found no change from the previous x-ray examination.

ANEURISM UNRECOGNIZED BY AUSCULTATION AND PERCUSSION SEEN BY AN X-RAY EXAMINATION.

CASE IX. (Fig. 6.) E. D., a neurasthenic woman, forty-two years old, referred to me from the Nervous Out-Patient Department of the Boston City Hospital by Dr. Knapp, after the Throat Department had reported to him complete paralysis of the left recurrent laryngeal nerve. It is interesting to note that the hoarseness, which led to suspicion of aneurism, had made no impression on the patient, because she had been somewhat hoarse since early school-days. Patient has suffered from nervousness for three years; lately easily tired, emotional and depressed. Hoarseness has increased since she has become emotional. Some dyspnea recently.

Physical examination.— Auscultation and percussion gave no signs of aneurism.

X-ray examination revealed a small aneurism of the aortic arch.

ANEURISM RECOGNIZED ONLY BY AN X-RAY EXAMINATION.

CASE X. (Fig. 7.) A. B., referred to Dr. Leland for esophageal stricture, and sent by him to me for an x-ray examination.

History.— In twenty-two years of married life her only pregnancy resulted in miscarriage. Patient was said to have a stricture about an inch below the upper end of the esophagus and another about opposite the second rib. During the past summer her family physician had passed an esophageal bougie every third day. Shortly before coming to me this treatment had been omitted and she felt no worse.

Physical examination gave no sign of thoracic aneurism.

X-ray examination revealed a small aneurism of the descending portion of the aortic arch. Its outline was plain whether viewed from front or behind.

This case suggests the advisability of an x-ray exam-

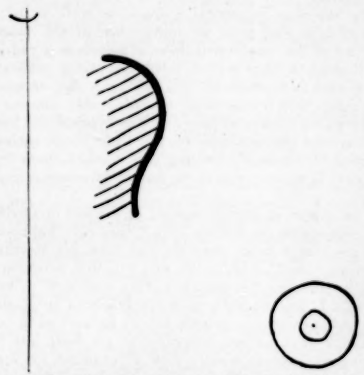

FIG. 7. Case X. About one-half original size.

ination before dilatation for esophageal constriction in some cases.

In conclusion, x-ray examinations should be made both with the fluorescent screen and the x-ray photograph. Normal outlines in the upper part of the chest give us the best assurance that an aneurism of the aorta is not present, though symptoms may obtain which lead the physician to suspect it. Outlines suggestive of aneurism may be caused by a new growth, for example. To make a definite diagnosis of aneurism by the usual physical examination we may be obliged to wait for the development of marked signs, and this delay defers treatment. Before operating on an aneurism near the thoracic aorta the latter artery should be examined by the x-rays, for if an aortic aneurism exists, operation would be unadvisable. X-ray examinations enable us to determine the extent of the aneurism, whether or not it is increasing, and in some cases to make a diagnosis before there are physical signs.

To Dr. William H. Rollins, who has done so much by his investigations to make the use of the Röntgen rays practicable in medicine, I desire to again express my obligation for his untiring helpfulness in my work.

A STERILIZER AND EQUIPMENT FOR CONFINEMENT CASES.[1]

BY FRANK A. HIGGINS, M.D., BOSTON,
Assistant in Obstetrics, Harvard Medical School; Physician to Out-Patients, Boston Lying-in Hospital.

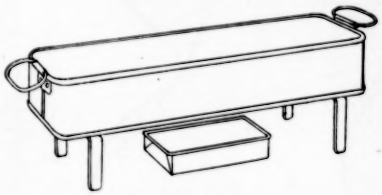
RECOGNIZING in my own practice the shortcomings and inconvenience of the ordinary obstetric bag and outfit as commonly sold in the surgical supply stores, and feeling the need of a more perfect yet not elaborate equipment, I have gotten together these things, which, so far as I have already been able to determine, answer the purpose for which they have been designed, and would also be sufficient for all except the most serious operative complications with which we are likely to meet in our obstetric work. Being frequently asked by the medical students with whom I come in contact and occasionally by a practitioner about the contents of my obstetric bag and what I am accustomed to carry to a normal confinement case, I have taken the liberty of showing my outfit to the Obstetrical Society.

By the man in general practice, as well as by the specialist in obstetrics, the importance of the careful practice of the simpler principles of asepsis as a routine in all cases of labor is now, I believe, pretty generally recognized and practised, and although one occasionally meets with a man doing a considerable amount of confinement work who has very little regard for asepsis and who perhaps uses only a little weak carbolic solution for his hands and neglects to wash them first, yet such instances seem to me now to be comparatively rare.

The almost universal custom at present of sterilizing instruments by boiling has, I dare say, impressed the need of a light, portable and compact sterilizer upon every one, as it has on me, who has occasion to boil instruments frequently in the ordinary private house. It has generally been my lot, both in general surgical operating in private houses as well as in confinement work before operating, to go down into the kitchen and search, usually with poor success, for some suitable basin or kettle in which the instruments may be boiled. To find such a utensil is more difficult for the obstetrical forceps than for the general surgical instruments, because of their length. Moreover, the doubt about such dishes being surgically clean, even after boiling, I have often questioned, and this point might arise to worry one in case of the occurrence of a subsequent sepsis. If there is a trained nurse at hand, who is known to be competent and faithful, such work is of course usually entrusted to her, and if she has been in the house long enough to have anticipated the possibility of an operation, she will probably have had a fish boiler or something equally good provided, but if such is not the case, as usually happens to the young man in practice, the difficulties are then his own.

Recognizing these facts, I have had made this small portable sterilizer, which seems to answer the purpose very well. It is practically only a covered box of nickel-plated sheet copper, approximately about fourteen inches long by five inches wide and two and three-quarters inches deep. The cover fits inside the top, and while not absolutely tight it is sufficiently so to prevent the escape of much steam. Inside on the bottom is the ordinary thin metal perforated tray on which the instruments lie. The tray, as well as the sterilizer itself, has swing handles which fold over and thus take up no extra room.

The sterilizer is designed so that it may be used either on top of the ordinary coal or gas range or with an alcohol lamp. The alcohol lamp with the sterilizer I have found very efficient for the purpose. It is a small metal box, two and a half by four and a half inches and seven-eighths of an inch deep, fitted with a cover. The box is filled with asbestos, which is covered with wire gauze. For fifteen minutes' boiling it requires about two ounces of alcohol and it burns with a very hot flame. When the lamp is used the sterilizer is raised by inserting the four small legs into the slots, one of which is seen at either corner. With the sterilizer about two-thirds full of cold water it boils with the alcohol lamp in six minutes; with hot water, which we would practically always have, and over a gas or coal range, there is no delay in the boiling. The sterilizer complete with the lamp weighs only about three pounds. It easily holds the obstetric forceps and what few other instruments are required in obstetric work. From my experience with it, it seems to me that its comparatively slight additional weight is much more than compensated for by its convenience and the increased comfort and safety one feels in its use. It readily fits into any operating bag, and as the instruments are carried in it, very little extra room in the bag is required. I believe that a sterilizer a little larger, slightly broader and deeper, made on the same plan would be sufficient for the instruments for any operation and would prove to be a great convenience to any surgeon who is operating frequently in private houses or outside of the city.



Sterilizer and lamp.

I wish to say, however, that the idea of a sterilizer for the obstetric bag was not original with me, but was first suggested, so far as I know, by Dr. C. M. Green, who had one made for his own use several years ago, but which I had not seen before mine was ordered.

Edgar has recently published [2] a description of a sterilizer designed for his own use in obstetric practice. It is made of enamelled sheet iron, and consists of two trays, a male and a female one, and which are large enough to contain his whole outfit. These trays he uses for sublimate solutions, for hot and cold water for the asphyxiated infant and also to boil the instruments. The trays are carried in a leather case instead of a travelling bag. This is certainly a more elaborate scheme, but does not seem to me to be necessary, as I have always found at hand in every house a number of porcelain chamber wash bowls which answer every purpose for sublimate and other solutions.

These instruments are carried in my sterilizer: Ob-

[1] Read before the Obstetrical Society of Boston, October 17, 1899.

[2] New York Medical Journal, June 17, 1899.

stetric forceps with axis-traction rods, pelvimeter, scissors, long dressing forceps, long double-hook volsellum, several artery forceps, scalpel, one long-handled perineum needle, several curved needles, long aspirating needle, glass curved douche tube, soft rubber catheter, long gum-elastic catheter.

In addition to the above instruments, all of which are easily contained in the sterilizer, the following articles are carried in the bag: Thin rubber apron, linen operating gown, four-quart fountain syringe, stethoscope, nail brush, can sterile gauze, collapsable tube, green soap (sterile), bottle fluid extract ergot, bottle alcohol, silkworm gut, chromicized catgut, rubber gloves, spring scales, hypodermic syringe and tablets, gag and tongue forceps, bottle sublimate tablets, bottle saline infusion tablets.

Ether, ergot, sublimate tablets, tincture of green soap, lysol, cheap nail brushes, absorbent cotton and bleached cheese-cloth should be and usually are provided by the better class of patients for use in their own households. Such patients as are in a position to employ trained nurses are always glad to purchase these articles as a part of their preparation, and the nurse will, if so taught, see that they are obtained. Ether, absorbent cotton and bleached gauze are always provided by my patients, but the other things named I still carry.

It has been my custom of late to use in tying the umbilical cord either catgut or silkworm gut in place of the usual tape or bobbin. I do this partly because being smaller it sinks in better and gives a better knot and a tighter grasp, and also because it is always at hand sterile and therefore saves an additional article to provide and have ready.

The rubber fountain syringe has replaced the old Davidson bulb syringe, and although the fountain syringe may be found in practically every house, yet in giving an intra-uterine douche or a subcutaneous saline infusion, the necessity of having a container which is known to be clean seems to me cannot be questioned. The syringe is sterilized by boiling and carried in a sterile towel. It is used quite infrequently, and therefore seldom removed from the package.

No styptic solution for the control of uterine postpartum hemorrhage is used, because gauze packing has proved to be equally efficient and better in every way. The can of baked gauze for the intra-uterine packing is one long strip for ease and safety in removal from the uterus. It is odorless, more convenient to prepare, and just as good for a styptic as iodoform gauze, which is usually recommended, and it will remain sweet for the comparatively short time which it is necessary to keep it in the uterus. The gauze purchased by the patient, twenty-five or fifty yards at three cents per yard, is to be made into vulvar pads and sponges and sterilized by the nurse.

I believe the small spring scales in general use are very inaccurate, but nothing else with which I am acquainted takes their place and most households are not provided with a suitable weighing balance.

There are only four bottles in the outfit, and of these only two contain liquids. The bottles themselves are heavy flint glass, with ground-glass stoppers and metal screw caps; the danger from breaking and leakage of liquids is therefore reduced to a minimum.

The canvas lithotomy sling is carried by some obstetricians, and is said to be very convenient in operative work when short of assistants. I believe it may be advisable to add it to the list.

I have found it very convenient to have a pair of rubber gloves ready for use under certain circumstances, although I do not make a practice of using them in every case, as advocated strenuously by some men. I believe it is comparatively easy to make the hands sufficiently aseptic for this work, and recent bacteriological work has proved that the normal vagina contains no pathogenic bacteria. Therefore it seems probable that the majority of infections occurring under ordinary precautions at the time of delivery are due to contact of the examining hand with the hairy labia. It is best when possible always to shave and scrub the external genitals, and thus remove, as far as may be, what is now generally accepted as the most likely source of infection.

This list of articles for the obstetric bag seems to me to be condensed about as far as consistent with the best work, and also to be elaborate enough to cope with any ordinary emergency. Any strong bag of moderate size, which will hold these things, is easily carried and suitable for the work. Personally I think it is better to have one which is not distinctive to the specialty.

ON THE HIGH OPERATION FOR DISEASE WITHIN THE SCROTUM.

BY J. G. MUMFORD, M.D., BOSTON.

There are certain distinct disadvantages in opening the scrotum for disease in that region. These disadvantages have long been recognized. The character of the skin and hair render disinfection difficult; the apposition accurately of cut edges is not easy; and the subsequent bandaging, cleansing, and care of the field are troublesome for the surgeon and extremely uncomfortable for the patient. This is true especially in such cases as long-standing hydrocele and hernia; for then the skin has become greatly stretched and its shrinking into folds subsequent to removal of the mass renders the proposition of primary union anything but simple — a proposition frequently solved, to be sure, but solved under peculiar disadvantages.

In the case of operation for large scrotal hernia, if the incision be carried from the internal ring to the apex of the scrotum, we have later to deal with a wound traversing two distinct varieties of skin and soft parts — a condition to be avoided always when possible.

In the ordinary Volkmann operation for hydrocele we have the scrotum alone opened, to be sure, but we have a relaxed bag left, instead of firm resisting tissues to deal with. The same statement holds true of such tumors as chronic orchitis, epididymitis and sarcoma. Moreover, after removal of the tumor in all these cases, a considerable hemorrhage is apt to persist, and the hemostasis is rendered so difficult that a secondary ooze and blood clot, with consequent increased risk of sepsis, result frequently.

In certain conditions, to be sure, the scrotum must be opened always. These conditions are malignant disease involving the skin and subcutaneous tissues, and tuberculosis or other burrowing suppurative disease.

Another disadvantage of the scrotal incision — a disadvantage the most important of all — is the great diffi-

culty of securing here an aseptic field, and the resulting condition of a loose, denuded cavity within the scrotum in immediate contact with a skin field but incompletely disinfected.

That all these things are very real dangers every surgeon knows. I doubt if there is another region of the body, presumably suited for aseptic work, in which our asepsis breaks down so frequently as in the scrotum.

The idea of the high operation for these scrotal diseases is no new one; but it was not until some two years ago, in a talk with Dr. Harvey W. Cushing, of Baltimore, that the applicability of the high operation to nearly all these cases was suggested to me. Since that time I have had many opportunities of applying the principle. I have come to regard it as a most useful procedure, and a distinct advance in the surgery of these parts.

The operation consists simply in making a short incision in the groin, similar to that made in the familiar Alexander operation for shortening the round ligaments. This incision opens a window through which all the contents of the scrotum can be reached with perfect ease. The field can be made surgically clean and kept so during convalescence, and the buried silver suture ensures a rapid healing. There is no wounded scrotum to support and protect, no slipping of bandages, no fouling with urine. The scrotum hangs naturally in its normal position and does not enter at all into the problem of after-treatment.

The first case in which I used this method was one of extensive varicocele. On opening down upon the structures about the cord, the usual two large tortuous veins were exposed and resected, and a small vein was left sufficient for the normal circulation of the parts. In such cases and by this method a beautiful anatomical demonstration is made. Nothing safer or more effective could be imagined. In all of these cases — and I have now employed this method in eight — the healing has been rapid and uncomplicated and the results satisfactory. In varicocele the method is most applicable.

Three cases of double orchidectomy for chronic hypertrophy of the prostate have come in my way, and in these cases the high operation has given gratifying results. When the cord and vessels have been exposed freely, and the wound made dry, the scrotum is invaginated and the testicle easily turned up into the wound in the manner so familiar in the radical cure of inguinal hernia. The scrotal contents may then be removed with a minimum of resulting hemorrhage and the cord and vessels separated and tied off intelligently and at leisure. A similar operation was done in a case of chronic epididymitis of long standing. The septic mass intact was removed through the high incision without infecting the wound. In this case there was much hemorrhage from the sac, and the persistent ooze resulted in a considerable clot, but the convalescence was rapid and complete. In such cases I recommend the free removal of the tunica vaginalis, else the secretion from its bruised serous surface will give rise to a considerable tumor.

It might appear that the radical cure of hydrocele by removal of the sac would be difficult when the high incision is employed, but such is not the case. A mass of moderate size may be delivered through the wound in the groin; and if the tumor be too large for this maneuvre, the fluid contents may be withdrawn, after which inversion of the scrotum is easy and the further steps of the operation self evident.

Large solid movable tumors within the scrotum may present some obstacles to the high method, but it is surprising to see how considerable a mass may be delivered, and if this be found impossible, a slight prolongation of the incision into the scrotal tissues will solve the problem readily.

Of the operation for scrotal hernia it is needless to speak. If the principle of the high incision be borne in mind the scrotum will not be opened in the great majority of cases, as the manipulation necessary for freeing the sac and its contents can be carried on easily without so doing.

Such examples show the applicability of the high operation for disease within the scrotum, and experience proves that this useful procedure may be employed in most cases of disease in this region.

Clinical Department.

A CASE OF PTOMAINE POISONING.

BY W. P. COUES, M.D., BOSTON.

P. M., age twenty-six, married, occupation inside man in a large store, had always been well and strong, with the exception of a rheumatic attack seven years ago. While at his work in Brookline the afternoon of April 24, 1899, he was seen suddenly to fall down, striking his face against the floor and breaking off part of a front tooth. A doctor was called, who, it was said, gave some medicine and sent him to his home in Boston in a carriage. He had left home early that morning feeling perfectly well, taking with him his luncheon, which consisted of chicken sandwiches and cocoanut pie; this was supplemented by some sardines obtained at his place of work. These facts I learned from the patient's wife and the friends who had brought him in the carriage from Brookline.

He was seen about 7 P. M. of the same evening. The result of the examination showed a large, well-developed man, in a condition of profound collapse. The extremities were cold, there was no pulse at the wrist, the man seemed *in extremis*. There was no bleeding from the nose or ears, the tongue was thrust out with difficulty, but in the median line. The patient was in a semi-conscious condition. The pupils were equal and reacted to light. The cardiac area of dulness was not increased.

The result of the examination of the lungs and the abdomen was entirely negative. The cardiac sounds could be made out with difficulty with the stethoscope. He complained of much pain and oppression in the precordial region, could only speak after great effort, and was constantly tossing about and rolling his head on the pillow. Heaters were placed around him, he was given strychnia, one-fifteenth grain, digitalis, fifteen minims, and shortly after, one-eighth grain morphia. His pulse after this was perceptible at the wrist, and the extremities grew warmer, he gradually responded to stimulation. He vomited twice, the vomitus consisting of finely divided, yellowish curds. His bowels moved, the movement being large and watery. The pulse remained for a long time very weak and thready, but he became more conscious and

spoke rationally. The next morning he was comfortable, pulse 100, temperature 100°. The urine showed one-eighth per cent. albumin; the sediment contained many fine granular casts. The albumin and casts disappeared in a few days, and the patient was soon as well as usual.

The points of interest in the case seem to be:

(1) The sudden onset of the trouble, which, with the previous rheumatic history, suggested collapse from cardiac disease.

(2) The profound shock, the pain in the precordial region.

(3) The nature of the last food taken, the vomiting, subsequent movement of the bowels, and gradual relief of symptoms.

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

MALCOLM STORER, M.D., SECRETARY.

Meeting of October 17, 1899, the President, Dr. Alfred Worcester, in the chair.

Dr. F. A. Higgins read a paper entitled

A STERILIZER AND OUTFIT FOR CONFINEMENT CASES.[1]

Dr. C. M. Green: This sterilizer is an improvement upon others on account of its lightness. My own is a great deal larger, large enough to sterilize many instruments which, on the other hand, often do not require to be sterilized. My sterilizer is a copper box without legs, and for heat I rely either upon the gas lamp that can be found in most houses or upon the kitchen range. My bag is based upon the principle of packing everything into the sterilizer except the rubber gown, douche bag and ether, and therefore my sterilizer is three times the size of Dr. Higgins's. After all, the individual apparatus one man or another uses is not of so much importance; the real merit of a paper like that of Dr. Higgins is to emphasize for the benefit of the medical public the necessity of doing aseptic work, which with an apparatus somewhat like this is not so very hard to carry out properly.

Dr. E. Reynolds: I can speak with much warmth about this sterilizer, for I regard it as just about what a sterilizer should be. My first impression was that it was too small for practical use, but a single trial convinced me of the contrary. It holds easily all that I need in an ordinary case. To be sure, I carry a few others besides those Dr. Higgins has enumerated — for instance, a set for an emergency symphyseotomy — but all go in easily. The quickness and power of the lamp that Dr. Higgins has shown is also a great comfort. I have the sterilizer all prepared at hand, and when the obstetrical climax approaches it is simply brought in and placed upon a convenient table and everything is ready for use a few moments after the lamp is lit. As regards the kit, personally I do not care to etherize a patient without having at hand a tracheotomy dilator, as well as the knife we always have. As regards gloves, I have become a thorough convert to their use in surgical work. I never operate or even make a vaginal examination without covering my hands with rubber, and I think that my results have not suffered thereby. In obstetrics I have employed them ever since they became easily obtained, using them often only upon one hand. I do not like to get vaginal mucus under my finger nails and possibly carry it from one patient to another. In many cases the preservation of the perineum is assisted by the shelling out of the head with one finger in the rectum, and in such cases it is a great advantage to have the hand covered, especially if it is subsequently necessary to do any operative work. The bare hand cannot be quickly disinfected, while it is easy to peel off the glove and have the hand already sterile.

Dr. J. B. Swift: I have been interested in Dr. Higgins's sterilizer because it is much like the one I carry. Mine is a little deeper. I carry all my instruments packed in the sterilizer. I have everything already sterilized at home and packed in canton flannel bags. I do this as it is not always convenient or indeed possible to get things sterilized at the bedside in time. I recognize the advantages in gloves Dr. Reynolds has spoken of. Dr. Swift then demonstrated his consultation bag.

Dr. Higgins: I had not seen Dr. Green's apparatus when I had mine made. I have sometimes thought that mine is a trifle small, but it has served very well in the class of cases for which it was intended — local and ordinary cases.

Dr. J. G. Blake spoke in the most complimentary terms of the thoroughness of the aseptic teaching given at the Harvard Medical school. As he saw cases in consultation, he was often much impressed by the accurate and complete observance of aseptic principles on the part of the younger general practitioners.

Dr. M. H. Richardson read a paper entitled

OVARIAN CYSTS WITH TWISTED PEDICLES.

Dr. Swift: I should like to inquire, whether in cases in which the operation is not done for some time after acute symptoms are seen it is customary to find an extensive general peritonitis.

Dr. Richardson: In all the cases in which there was delay the tumor was totally adherent.

Dr. Swift: In a case of mine last spring in which there was considerable unavoidable delay I found the tumor so firmly adherent everywhere and especially to the posterior side of the uterus that I had to remove the uterus with the tumor. The patient died septic, probably from a tear of the rectum, though none was seen at the operation.

Dr. E. Reynolds: I have seen five cases of the strangulation of ovarian tumors. The only one without adhesions was a solid tumor of the ovary, the walls of which were extremely friable, and the peritoneum red and rough. She died of embolus, presumably of septic nature. In this case the blood supply was cut off immediately after labor, there being no real torsion. In another case, in which hysterectomy for sepsis was being done by a distinguished obstetrician, upon opening the abdomen a strangulated ovarian tumor was found, apparently caused by delivery.

Dr. F. H. Davenport referred to the peculiar friability of these tumors and instanced a case of his in which there were few adhesions but it was almost impossible to get the tumor out whole.

Dr. J. C. Munro: I remember two cases in which the twist was so near the uterus that I had to tie off very close indeed to it. As regards the difficulty of

[1] See page 88 of the Journal.

diagnosis, I remember one case in which the diagnosis of appendicitis was made, and another seen in consultation with a number of the staff which was generally regarded as one of pregnancy associated with pyosalpinx.

DR. H. E. MARION: My experience in this interesting condition is limited to two cases, oddly enough seen on the same day, one of them coming in Dr. Richardson's list.

DR. W. L. BURRAGE: In looking over my notes I find that I have seen five cases, four of them being in women over sixty-one, the fifth being in a girl of thirteen thought by her friends to be pregnant. In one case the patient was an extremely feeble old woman, but recovery after operation was prompt. I think we ought to distinguish very carefully between mere twist and actual strangulation.

DR. MALCOLM STORER: I am glad to hear Dr. Burrage make this distinction. In a paper[2] read before this Society some years ago, I stated that an average of the observations of a number of men shows that rotation occurs in at least 25 to 35 per cent. of all ovarian tumors, but actual strangulation in only 8 to 11 per cent. In the four cases which I have myself operated upon, in two in which there were two or three twists there was no reaction on the part of the tumor or of the patient. The third case was an old woman, with obscure history and in very bad condition, whom I saw just at the change of a service and foolishly deferred operation. Dr. Burrage subsequently operated with success. My fourth case was in a woman five months pregnant. She had had three attacks of typical pain within a few weeks. I operated and found a tumor with three twists slightly adherent. She brought the child into my office a few days ago to show me. Dr. Burrage has asked my opinion as to the causation of these torsions. My reading has led me to believe with Dr. Richardson that many causes may produce a twist, but that it is especially apt to occur in more or less irregular tumors, the projections acting like ratchets. Mouls and Reboul have mentioned two pathognomonic signs: a systolic murmur at the tender point and a pulsating movement of the tumor coincident with the cardiac beat.

DR. RICHARDSON: I want again to emphasize the difficulty of diagnosis. In one case no tumor could be felt, yet two weeks later there was one filling the abdomen. Any abdominal tumor that is tender and associated with shock should excite suspicion. I have been struck by the comparatively slight symptoms in some of these cases that had extended over some time.

DR. REYNOLDS suggested that the sudden increase in size of these tumors might lead to a sudden sweating, so to say, and thus cause adhesions and pain.

DR. COUNCILMAN: I should hardly think the easily broken up adhesions Dr. Richardson speaks of were real connective-tissue adhesions, being more likely mere fibrin.

BEQUESTS OF DR. DANIEL GARRISON BRINTON.—The late Dr. Brinton, formerly the editor of the *Medical and Surgical Reporter*, has bequeathed to the University of Pennsylvania his valuable library and manuscripts relating to the science of ethnology, a branch of learning to which the latter part of his life was mainly devoted.

---

[2] Boston Medical and Surgical Journal, November 5, 1896.

Recent Literature.

Enlargement of the Prostate; its Treatment and Radical Cure. By C. MANSELL MOULLIN, M.D. (Oxon.), F.R.C.S. Second edition. Pp. 205. London: H. K. Lewis. Philadelphia: P. Blakiston's Son & Co. 1899.

The first edition of this book was published at a time when radical operations upon the prostate had passed the probationary period of their development, but were still by no means upon so firm a footing as to be beyond the attacks of their opponents. The writer announced himself as a champion of such radical operations, and in his preface said, "And now it is not too much to say that perfect relief can be assured even in the most advanced stages of the disorder."

The second edition brings the book well up to the present-day knowledge of the subject, and, omitting descriptions of many of the older operative procedures, now chiefly of historic interest, confines itself to those whose practical value is vouched for by the writer's knowledge and large experience.

Of the eleven chapters which the book contains, nine are devoted to a consideration of the (1) normal prostate, its function and development, and (2) the enlarged prostate, its causes, effects upon other organs, its symptoms, diagnosis and palliative treatment, both local and general.

The last two chapters take up the various radical operations and the problems they involve. In his preface to the present second edition, the writer has evidenced his faith in the efficacy of such operations by saying: "There is now no case of enlargement in which perfect relief cannot be obtained, provided only the secondary consequences, which so often and so entirely unnecessarily follow it, and which are due in the vast majority of instances to the careless use of catheters, have not been allowed to work irreparable harm upon the walls of the bladder. In no department of surgery are the disastrous results of temporizing and delay shown more clearly than in that which is concerned with the prostate."

The various radical operations are carefully considered and the place for each is defined. In speaking of ligature and division of the vas deferens as a substitute for orchidectomy, the author is evidently of the opinion that orchidectomy is much to be preferred and that ligature is suited only to a very limited class of cases. The Bottini operation is favorably commented upon and the author's three successful cases are mentioned but not fully reported. The book merits the attention it will undoubtedly command from the surgical profession.

An American Text-Book of the Diseases of the Eye, Ear, Nose and Throat. Edited by G. E. DE SCHWEINITZ, A.M., M.D., Professor of Ophthalmology in the Jefferson Medical College, Philadelphia, etc., and B. ALEX. RANDALL, M.A., M.D., Ph.D., Clinical Professor of Diseases of the Ear in the University of Pennsylvania, etc. Pp. 1,251. Illustrated with 766 engravings, 59 of them in colors. Philadelphia: W. B. Saunders. 1899.

In the portion of the work devoted to the eye, its embryology, anatomy, histology, physiology, diseases and injuries are discussed in twenty-four sections by

twenty-four authors; its operative surgery in seven sections by as many authors. In the portion of the work devoted to the ear, its anatomy, physiology, diseases and injuries are discussed in thirteen sections by fourteen authors, while diseases of the nose and throat are described in twenty sections by nineteen authors.

As the work aims to be both a text-book and a volume of reference to which the practitioner may turn, the practical side of the questions discussed has been brought into prominence.

All the contributions have evidently been written with great care. The articles are, as a rule, comprehensive and accurate, and an absence of padding characterizes the entire work. The suggestions with regard to treatment have been brought up to date more nearly than in some of the collaborative works that have been lately published. The gentlemen who have been asked to write are all well-known practitioners of the highest skill, and perhaps no better praise can be given in this journal than to publish the list of the Boston contributors, who are: Dr. Clarence J. Blake, Dr. J. Orne Green, Dr. John W. Farlow, Dr. Geo. A. Leland and Dr. J. H. McCollom.

The publishers have done their part of the work well, and the paper, type and illustrations are all that could be desired.

Surgical Nursing. By Bertha M. Voswinkel, Graduate of Episcopal Hospital, Philadelphia, etc. Second edition, revised and enlarged. Pp. 206, with 112 illustrations. Philadelphia: P. Blakiston's Son & Co. 1899.

This book has been written, its writer states, for nurses whose surgical training has been limited and whose technical education is not sufficient to render them thoroughly conversant with all its details. An attempt has been made "to give a concise outline of surgical nursing in general, together with a list of antiseptic agents, the mode of preparation of the various materials used in aseptic and antiseptic surgery, and finally the application of splints and fixed dressings."

As one reads the book the impression is created that it was written by one whose training has been local rather than general, and whose experience has been acquired from hospitals rather than in private work, also that the subject under consideration is not always kept in view. As an illustration the following quotations are made:

"In case of an emergency when an antiseptic dressing is required and no gauze is at hand, absorbent cotton may be used, first baking it for a few minutes in an oven; then wet it with bichloride solution, then dry, and keep in cheese-cloth bags." In describing the use of instruments at an operation it is directed that soiled instruments, presumably those dropped on the floor, or otherwise accidentally infected, are to be cleaned by rinsing in a tray of hot water before being again placed in use. For the "nurse whose surgical training has been limited," it is somewhat disappointing to find that in the whole book the only statement relating to the sterilization of instruments is that "All instruments should be thoroughly sterilized before and after using."

We are familiar with Thiersch's solution and Professor Kocher's method of preparing catgut, but have not heard of the borosalicylic solution highly recommended by "Tersch," or the catgut of "Koscher." Neither have we seen a "mouth"-tooth forceps. The work of the publisher is quite satisfactory. The book is conveniently indexed, contains a great deal of information, a knowledge of which is essential to the modern surgical nurse, and for some reason or other it has reached a second edition.

A Practical Treatise on Materia Medica and Therapeutics. By Robert Bartholow, M.A., M.D., LL.D., Professor Emeritus of Materia Medica, General Therapeutics and Hygiene, in the Jefferson Medical College of Philadelphia; formerly Professor of Materia Medica and Therapeutics and of the Practice of Medicine in the Medical College of Ohio, etc. Tenth edition, revised and enlarged. New York: D. Appleton and Company. 1899.

There are such good books already published on this subject that a new work or even a new edition of an old one is only justified when it furnishes some substantial addition to our present knowledge. This cannot be claimed for the above volume. Far from deserving praise, it merits disapproval, because it contains so many erroneous statements and shows so scant an acquaintance with the present medical literature.

One is constantly meeting passages like the following, on page 30: "Within the present year (1880) Mr. Arthur Meldon has published an account of three cases in which the transfusion of milk was performed with success." As authority for another remark, he considers the *New York Medical Journal* for February 3, 1883, a recent issue, page 31. The eighth edition of the author's own work was published in 1893. Under "authorities referred to" on transfusion, the latest date given is 1886.

We fail to understand the author's position when he says, page 34: "Although fat is necessary to the stomach digestion, it does not undergo conversion in the stomach, and escapes in a coarse emulsion, with the chyme, into the duodenum." We should like to know the experimental basis on which this conclusion rests.

"Arsenic" (page 75) "has seemed to the author remarkably beneficial in diabetes of hepatic origin." But the experience of the profession does not confirm the truth of this statement and that this is published in the tenth edition of a book on therapeutics is inexcusable. In the clinical index is to be found under diabetes, "The milk cure has succeeded remarkably in some cases; buttermilk *may* be better." And in the text, page 60, "In consequence of the large proportion of lactic acid which it contains, buttermilk is more especially indicated in diabetes."

Those interested in children's diseases will certainly be somewhat taken aback to learn that, page 60, "In the author's experience, children, with few exceptions, do well on condensed milk." And so we might go on. Such a book is unworthy of the medicine of to-day.

Selected Papers on Stone, Prostate and Other Urinary Disorders. By Reginald Harrison, F.R.C.S. Pp. 190, with 15 illustrations. London: J. and A. Churchill. Philadelphia: P. Blakiston's Son & Co. 1899.

This little book is made up of a collection of sixteen articles which have appeared from time to time, during the last half dozen years, in various periodicals, chiefly of English publication. The chapters have no sequence or connection with one another, and are written for the surgeon rather than for the student of medi-

cine. The first article, Vesical Stone and Prostatic Disorders, was the Bradshaw Lecture delivered at the Royal College of Surgeons in December, 1896, and consists of a necessarily brief résumé of this large subject. It is followed by a chapter headed, A Further Contribution to the Surgery of Stone in the Bladder, and containing a table of the author's cases of stone, 110 in number, treated by litholapaxy during the years 1890–97.

The other articles cover a wide range of genito-urinary subjects of interest at the present day. All are short, all are written in an attractive and readable way, and all give glimpses of Mr. Harrison's great experience, which will be welcomed by readers interested in genito-urinary surgery.

Raynaud's Disease (Local Syncope, Local Asphyxia, Symmetrical Gangrene), its History, Causes, Symptoms, Morbid Relations, Pathology and Treatment. By THOMAS KIRKPATRICK MONRO, M.A., M.D. Pp. xii, 251. Glasgow: James Maclehose & Sons. 1899.

The present monograph gives an excellent account of this rare affection based upon a careful study of the literature, from which the writer has collected and tabulated one hundred and eighty cases. It begins most appropriately with a brief biography of Maurice Raynaud, whose original description of the affection has been but slightly modified by subsequent researches. The author, in fact, at the end of his labors, returns to Raynaud's original theory that local syncope and asphyxia are due to spasm of the small vessels, which, if unduly prolonged, leads to gangrene; and that this spasm depends upon an abnormal excitability of the vasomotor centres in the spinal cord. The theory that the trouble is due to peripheral neuritis is, after careful consideration, rejected. To all who may be interested in Raynaud's disease the volume will afford a very complete summary of our present knowledge.

Minor Surgery and Bandaging. By HENRY R. WHARTON, M.D., Surgeon to the Presbyterian Hospital, etc. Fourth edition, revised and enlarged. Pp. 594, with 502 engravings, many being photographic. Philadelphia and New York: Lea Bros. & Co. 1899.

The demand for this book is shown by the fact that it has reached its fourth edition in a period of eight years. This fact also is evidence of the energy of its author and his desire to maintain a high standard of excellence in regard to the work and to have it an exponent of the most modern ideas. In addition to a careful revision, the new feature of the present volume is the addition of a chapter on Surgical Bacteriology, which is a brief résumé of the subject, also the section devoted to Operative Procedures on the Cadaver, including descriptions of not only the usual typical ligations, amputations, resections and excisions, but also some atypical ones, such as esophagotomy, gastrostomy, pyloroplasty, intestinal suture and anastomosis, osteotomy, etc. The descriptions are brief and are not intended to take the place of elaborate and fully detailed ones given in special works on operative surgery. The list of illustrations has also been increased. The section on Bandaging describes the various applications of roller bandages. If the initial and terminal ends were more clearly designated in some of the illustrations the student would be saved some study.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, JANUARY 25, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

THE DISPERSION OF BEQUESTS.

WITH the constantly increasing tendency toward the accumulation of wealth in the hands of single individuals, the ultimate disposition of that money becomes of more and more importance. Charitable objects in general are no doubt claiming greater recognition than ever before, and among such charitable objects the hospital is being accorded an important place. A tendency which, on the whole, is unfortunate is also observable, and that is that in the final distribution of single great fortunes new enterprises are often inaugurated which in themselves are not particularly needed. We have had ample demonstration of this fact in America in the founding, for example, of new universities in the immediate vicinity of old established institutions, in consequence of the bequest of a single individual. This process of multiplication shows no evidence of abatement; on the other hand as individual collections of money grow larger, thereby rendering possible the foundation and at least temporary support of a newly-fledged institution, the temptation to men of means and personal ambition is constantly increasing to put their money into an object which will be definitely associated with their names in the years to come. The general cause of education and of charity no doubt suffers in the long run through this multiplication of existing institutions. What we need is concentration, and for various reasons.

In the first place, the question of expense is of paramount importance. It is a self-evident fact that a preliminary problem merely is solved when buildings are equipped and an institution started on its course of usefulness. Experience has shown that the strain comes when continued support of the institution is demanded, as demanded it must be as soon as it enters upon its active work and is forced to meet the exigencies of improved methods and widening knowledge. As a consequence of this need for increased resources, which frequently are not forthcoming, institutions started by single-man beneficence are apt to

languish when the original source of income fails. To endow an institution in perpetuity is nowadays quite impossible, because one is absolutely unable to see the extent and direction of the expansion of its work in the future. Who could have foreseen, for example, thirty years ago, that expensively equipped laboratories would so soon come to form a necessary adjunct to the modern hospital, or that elaborate arrangements for sterilization and buildings of special construction would be essential to the proper care of the sick? This inevitable expansion always demands large pecuniary resources, and, in consequence, many institutions are now being restricted in their work, because money which might otherwise have come to them is being constantly directed into other channels, leading to the foundation of new institutions of various sorts. This is not economy. It means a duplication of much that already exists, and is quite capable of expansion at a much less expense than is necessitated by an entirely new plant, with its complicated machinery of paid officials and all that goes with the management and conduct of a new institution of whatsoever sort.

What we have said is true of many great public enterprises, educational or otherwise, and applies with particular force to hospitals. A modern hospital is an enormously expensive institution to conduct in a progressive way; its buildings and equipment lack in a peculiar manner the elements of permanency. What is useful to-day may be discarded to-morrow, and improvements of various sorts are an almost daily demand. Since this is so, it is always a matter of regret that sums of money of considerable, as of small, amount should not be left to institutions already in existence, or to seats of learning, which have the confidence of the public, and which would expend such money in the most economical and judicious way to the end of improving medical education and the care of the sick. If it be desirable to have a hospital for the care of those ill with chronic disease, which, as we have frequently had occasion to express, seems to us a crying need, why not establish such a hospital as a department of one already existing, or build a new one in connection with some public or corporate institution, which would stand behind it in the years of growth and development which are sure to come, attract to it fresh endowments and thereby preclude the failure of a naturally expensive undertaking. Otherwise the tendency must be toward disintegration and toward the ultimate multiplication of institutions to the good of none, and to the probable detriment of all. What we need above all things are hospitals strong in resources and not merely in brick and mortar. Whether or not a hospital can be advantageously conducted by an educational institution is a question which merits separate consideration.

But from every point of view, it seems to us desirable that public sentiment should be directed in such a way that gifts of money, by will or otherwise, should go toward the improvement of institutions already in existence, or toward the founding of departments in close touch with established institutions of broad scope and ample means to ensure the safety and continuance of the work of the new enterprise.

THE WOUNDED IN SOUTH AFRICA.

Reports are rapidly coming from the seat of war in South Africa which bear out the more limited experience of our late war with Spain regarding the effect of the modern rifle bullet, and particularly of the Mauser, which is now universally regarded as the most humane of those in use. Sir William MacCormac, writing to the *Lancet*, gives various exceedingly interesting details regarding wounds inflicted by Mauser bullets, wounds which a few years ago would have been thought quite incompatible with life. Sir William says: "One cannot help contrasting with amazement the comparative harmlessness of the injuries so frequently inflicted with the Mauser rifle bullet with the frightful extent of the damage done by those of the needle-gun and the Chassepôt. To any one familiar with the wounds caused by these weapons, many of those inflicted by the Mauser rifle might be regarded as being somewhat of the character of a 'pin-prick.' Quite a large proportion of the wounded, in fact, have returned to duty, and several patients whom I have seen have been wounded for the second time at another engagement."

Some of the cases recorded are as follows: A man was struck by a Mauser bullet an inch above the symphysis pubis, the exit wound being one inch above the level of the anus and somewhat to one side. After being wounded he ran about one-third of a mile without inconvenience, and at the end of a fortnight had completely recovered. A soldier was shot in such a way that the bullet passed through the stomach after having penetrated the ilium. The patient suffered no inconvenience whatever, and was able to eat as usual. A bullet wound through the skull with protrusion of brain substance, dressed on the field, gave rise to no symptoms, and the wounds were healed on the fourth day. Penetrating wounds of the lungs in several instances recorded were followed by a quick recovery.

These are some of the cases to which special allusion is made, and it is certainly not too much to say, as has elsewhere been suggested, that the surgical aspects of bullet wounds must be largely rewritten, in view of the present unfortunate rapidly accumulating experience.

On the other hand it would appear that the Mauser is not always so merciful as the above cases would seem to indicate. Surgeon C. Marsh Beadnell, in a letter to the *British Medical Journal*, speaks, for example, of a poor fellow "raving mad, who had been wandering about for hours with a portion of his frontal lobe protruding through a Mauser exit wound in the fore part of his skull." Another case of considerable

interest reported by the same writer, relative to the effect of the shock of an exploding shell, is as follows: "A shell exploded about ten yards over a Highlander's head; he was untouched by any fragments, but the concussion must have produced some curious pathological change in his nervous system, as he has never ceased (now ten hours) swaying his head to and fro with a pendulum-like motion similar to that of the china dolls with the nodding head so commonly seen in the London streets. His intellectual faculties have also been considerably disturbed, as he is only half rational." A collection of such cases bearing upon the effects of battle, mechanical or otherwise, would be of great value toward determining certain difficult points in connection with the results of trauma upon the nervous system, as we have previously had occasion to suggest in these columns. In general, we may certainly look for a large collection of data from medical men in the field which will prove of lasting scientific value; a poor compensation, but still a slight one, for the wholesale suffering which such a war of necessity entails.

Dr. Beadnell concludes from his investigations on the effect of bullet wounds that those wounds which heal up most rapidly and give the least trouble are wounds produced by bullets having these characteristics:

(1) A very high velocity.
(2) A flat trajectory, so that they hit apex first and do not keyhole.
(3) A hard smooth sheath with a smooth rounded apex.
(4) A close range, for the same reason as (2) a bullet at a long range may hit the object side on.

He says: "If I were to tabulate these missiles in the order in which the wounds produced by them were progressively more serious from above downwards, the table would read something as follows:

"(1) Mauser.
"(2) Krag-Jorgensen.
"(3) Lee-Metford.
"(4) Man-stopping Lee-Metford (hollow-headed nickel-sheathed).
"(5) Any of the first three with the nickel sheaths around the apex removed so that the lead nucleus is exposed.
"(6) Dum-dum.
"(7) Remington brass-coated, as used by the Filipinos.
"(8) Remington lead bullets or the Martini-Henry.
"(9) Remington brass bullet, with brass sheathing removed so as to expose the lead nucleus.
"(10) Shrapnel bullets.
"(11) Shell or their fragments.

"I have no acquaintance with explosive bullets; it is said the Boers have used them, but I think this to be exceedingly doubtful. Most thoughtful men will agree that the Boers have proved themselves to be brave men, and instances of a violation of the laws of civilized warfare are few and far between."

In general, the health of the troops appears to have been excellent; diarrhea, sunstroke and sunburn have been the most annoying maladies.

With regard to the latter trouble, the report continues: "The Highlanders are chiefly afflicted; why are men sent out in this fierce sun in petticoats? It is all very well to talk about the uniform being the essence of *esprit de corps*, but is not this carrying it too far? Surely they might be allowed to go into action at any rate as other men go. As it is, their legs become covered with crops of vesicles; few of the men like their dress for this kind of work; the beauty of the kilt and sporran is masked by a khaki flap, and when these two part company the aspect is both ludicrous and alarming; I saw one man returning yesterday from his brush with the enemy in a pitiable plight; in his own words, he had had to 'take' a barbed wire entanglement 'at the double,' and emerged 'a bleeding mass, with kilt hard a starboard, his khaki flap half-left turn, and his sporran dangling on the wire.'"

MEDICAL NOTES.

THE PLAGUE SITUATION. — Reports from Honolulu regarding plague are such as to excite considerable apprehension. The number of cases is increasing rapidly, and measures have been adopted by the Board of Health to burn infected buildings in the Chinese quarter, where the disease appears to have gained a foothold. Quarantine is strict and there is fear that the industry of the island, which lies chiefly in sugar, may be seriously hampered. Statistics reported to the Surgeon-General of the Marine-Hospital Service, ending January 19th, show cases from various countries, in part as follows: Honolulu, up to January 16th, 5 cases; Philippine Islands, 5 cases; Brazil, up to December 23d, 38 cases; China, 42; Japan, 13; Portugal, 10 cases and 7 deaths.

HOSPITAL STAFF FOR MANILA. — The War Department is reported to have arranged to send 150 hospital-corps men to the Philippines on the hospital ship *Missouri*, which is to sail from San Francisco some time next month. Acting Hospital Steward Cleveland Hilson, Jr., and 41 privates of the hospital corps, now at the Washington Barracks, D. C., will start for San Francisco in a few days.

FAMINE IN INDIA. — The famine situation in India is reported as worse than ever before. About 22,000,000 persons are now affected in British territory, and about 27,000,000 in the native states. The Viceroy, Lord Curzon, reports that the famine area has expanded, and they are now facing a cattle, water and food scarcity of a terrible character. About 3,250,000 persons are already receiving relief.

SMALL-POX IN INDIANA. — Small-pox is reported as prevalent in fourteen counties of the State. A recent report to the Board of Health showed 15 new cases in Clay County, and nine new cases from Vanderburg County. A general disinfection of the mails coming from infected districts will be undertaken.

STATE CARE OF TUBERCULOSIS PATIENTS. — At the coming meeting of the Medical Society of the State of New York special prominence will be given

to a discussion of the questions relating to State care of tuberculosis patients.

Arrival of the "Maine." — The American hospital ship *Maine* has arrived at Cape Town, South Africa.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the week ending at noon, January 24, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 100, scarlatina 51, measles 66, typhoid fever 10.

Annual Meeting of the Boston Lying-in Hospital. — At the annual meeting of the Boston Lying-in Hospital Corporation officers were elected as follows: Nathaniel Thayer, President; Hon. Henry H. Sprague, Vice-President; Hon. George v. L. Meyer, Treasurer; William D. Sohier, Secretary, and William H. Baldwin, Thomas F. Edmands, Oliver Ames, Charles W. Hubbard, Wallace L. Pierce and Samuel Wells, Trustees. With them are associated Dr. J. Collins Warren and Dr. George B. Shattuck, from the Massachusetts Humane Society, and Hon. George G. Crocker and James G. Freeman, from the Massachusetts Charitable Fire Society. The hospital has taken care of more mothers during childbirth than last year, 647 patients having been treated in the hospital, 652 children were born there, and there were four deaths during confinement.

Diphtheria and Scarlet Fever Prevalent in Boston — There is a large amount of both scarlet fever and diphtheria in many wards of the city. Up to the latter part of last week 236 cases of diphtheria and 132 cases of scarlet fever had been reported to the Board of Health this year; the numbers are greatly in excess of the records for the corresponding period of last year. One of the reasons why these diseases are spreading is that there is a lack of accommodation at the City Hospital for the isolation of the patients. In many instances the victims of the diseases cannot be removed from their homes, and be isolated properly, for the reason that the Board of Health has no other place to which to remove them.

Boston Society of Medical Sciences. — A meeting of this Society was held January 16th, at which the following communications were presented. Dr. Mark W. Richardson read a paper on the "Cultivation of the Typhoid Bacillus from Rose Spots," and spoke of his own investigations on the subject. Dr. Theobald Smith spoke on the "Significance of Variation among Pathogenic Bacteria." Dr. J. H. Wright demonstrated an ingenious and simple method for anaërobic cultivation of bacteria in fluid media. Dr. E. W. Taylor showed a series of lantern slides illustrating various lesions of the nervous system.

The West End Nursery. — At the annual meeting of the corporation of the West End Nursery and Infants' Hospital the following officers were elected for the year 1900: President, Oliver Ames; Secretary, William Rotch; Treasurer, Nelson S. Bartlett; Directors, Frederick B. Allen, J. Arthur Beebe, Clarence John Blake, George A. Draper, Charles E. Inches, Mortimer B. Mason and T. M. Rotch. Two hundred and fifty sick infants have been admitted to the wards during the past year and 11,231 visits have been made to the Out-Patient Department.

Illness at Harvard University during the Year 1898–99. — The official statistical report of illness at the University shows a larger grand total than during the preceding year, but a decrease in cases of contagious diseases and injuries. The report says the latter is undoubtedly due to "more intelligent management of athletics." Among other specified disorders there were five cases of typhoid fever, 48 cases of measles, 126 headaches and seven instances of overwork. The value of statistics of this sort is not altogether apparent.

Advice to Prospective Medical Students. — The committee in the department of zoölogy in Harvard University has recommended to the Board of Overseers that undergraduates about to study medicine be advised to attend a preliminary course on the anatomy of the vertebrates and invertebrates, as well as two preliminary courses in zoölogy. The committee furthermore suggests the desirability of arranging that certain courses in the academic department should be counted in the term of medical study.

Compulsory Vaccination in Malden. — Through the investigation of the Board of Health it has been ordered, owing to the existence of a case of small-pox in Malden, that all school children must be vaccinated, and must show evidence of successful vaccination in order to be allowed to attend school February 5th. Many have not yet complied with the order.

Further Bequest for Harvard Infirmary. — It is reported that Mr. Stillman, of New York, who gave $50,000 last year for an infirmary at Harvard University, Cambridge, has recently added $50,000 more, to be used by the building committee at their discretion. Work on the building will be begun early in the spring.

Infectious Diseases in Outlying Towns. — Three schools were closed last week in Reading, Mass., on account of the prevalence of diphtheria. It is reported that 29 cases have appeared since December 20th. Fewer cases are reported from Cambridge, Newton and Brookline.

Endowment Fund for Newton, Mass., Hospital. — At a recent meeting of the Newton Hospital Aid Association, it was voted to establish an endowment fund for the benefit of the hospital.

NEW YORK.

Proposed Precautions against Premature Burial. — At a meeting of the Board of Health held January 17th a communication was received from Dr. H. J. Garrigues, chairman of a committee from the Society of Medical Jurisprudence, recommending such alteration of the sanitary code as will better guard

against premature burial; and provision was made for a conference of the Sanitary Committee of the Department with Dr. Garrigues's committee in relation to the matter. The communication recommends that only authorized practitioners of medicine shall decide whether a person is dead or not, and suggests a change in the blank forms of death certificates so that they be made to contain the declaration that the physician personally has examined the body. It is furthermore recommended that the chief signs of death be enumerated in the blank, and that the physician shall indicate the presence or absence of each with "Yes" or "No." Finally, it is suggested that by ordinance it be made illegal "to do anything to the body of the supposed dead which, if he were alive, would cause him pain or injure him, before the certificate of his death has been signed by the physician." With a view to the prevention of premature burials, a bill has been introduced in the Legislature which provides: (1) That no human body shall be buried in the State without the use of such apparatus or mechanical means as may be approved of by the State Board of Health, which will permit of the person whose body is so interred obtaining assistance from living persons in the event of such person having been in a state of lethargy or coma at the time of burial; (2) that any person violating the provisions of this act shall, if the person interred in violation thereof shall be proved to have been prematurely buried, be guilty of a felony, and if the person so interred shall not be proved to have been prematurely buried shall be guilty of a misdemeanor. No exception is apparently made in the case of those upon whom autopsies have been made.

INTERNATIONAL ORDER OF DOUBLE CROSS. — On January 1st, the International Order of the Double Cross, the object of which is the extension of Christianity by the combination of religious effort and medical services, was organized at a meeting held at the headquarters of the International Medical Missionary Society, on East 45th Street. Dr. G. Dowkontt, medical director of the latter Society, presided, and the twenty founders of the Order present represented ten different nationalities. Of these, ten were physicians, six medical students, and four trained nurses. One of the purposes of the Order is the uniting of all medical missions and medical missionaries throughout the world, and the active membership, which is open to persons of both sexes, is to be divided into four guilds, physicians, medical students, nurses and helpers, while all medical missionaries are to be considered as honorary members. The emblem of the Order, from which it takes its name, consists of the double cross formed by the crosses of St. George and St. Andrew. The following officers were elected at the meeting: President, Dr. G. D. Dowkontt; Secretary, Cyril H. Haas; Treasurer, the Rev. W. W. Smith, M.D.; Registrar, the Rev. Theodore F. Hahn. These four officials, together with Drs. John H. Busteel, Wm. Steward and H. Zeckhausen, constitute the Executive Council for 1900.

THE MONTEFIORE HOME FOR CHRONIC INVALIDS. — The directors of this institution have begun the erection of new buildings at the county sanitarium of the institution at Bedford Station, Westchester County, which will increase its capacity to 300 patients. It is used exclusively for those suffering from pulmonary disease, and very good results have been obtained there. The annual report of the Home, just issued, shows that at the city hospital and the county sanitarium there were treated during the year a total of 609 patients, of whom only eight were pay patients; 8.21 per cent. were discharged as cured, and the death-rate for the year was 16.91, the lowest since the establishment of the Home. One admirable feature of this institution is the Discharged Patients' Fund, maintained through the generosity of the directors, by means of which such persons are given pecuniary assistance until they are able to secure employment. During the year $1,021 was used for this purpose, 91 persons receiving aid in sums ranging from $34 to $5.00.

PENSIONS FOR MEDICAL OFFICERS. — The following bill has been introduced in the Legislature: Providing that any medical officer in the service of the State hospitals who may be physically disabled by reason of any injury or illness incurred in the discharge of his duties shall receive a pension. At a meeting of the New York County Medical Association held January 15th a resolution was adopted endorsing and recommending its endorsement by the New York State Medical Association and the American Medical Association, the bill introduced in the United States Senate by Senator T. C. Platt, for the purpose of giving the same status to acting assistant surgeons of the United States Army that is given to the acting assistant surgeons of the navy.

BOTANICAL GARDEN. — At the annual meeting of the corporation of the New York Botanical Garden, held January 8th, Dr. N. L. Britton, the Secretary and Director-in-Chief, reviewed in his report the work accomplished last year on the grounds and buildings of the garden in Bronx Park. The tract occupied includes 250 acres, and the number of species and varieties of vegetable life under cultivation and native to the grounds is now over 4,000. At the meeting Dr. W. Gilman Thompson was elected a manager.

PORTRAIT OF PROFESSOR METCALFE. — Dr. T. Gaillard Thomas has presented to the New York Academy of Medicine a fine portrait of Prof. John T. Metcalfe, painted by the late Jacob H. Lazarus. Since his retirement from active practice, some years ago, Dr. Metcalfe has been in the habit of spending his winters at Thomasville, Ga., and the rest of the year at Cold Spring, on the Hudson.

DISMISSAL OF A HOSPITAL HOUSE STAFF. — The entire house staff of the Metropolitan Hospital (homeopathic) on Blackwell's Island, consisting of twelve members, has been dismissed by the Commissioner of Public Charities, on account of an act of

discourtesy to the superintendent of the hospital, who had incurred the animosity of the young men.

PHILADELPHIA.

FRAUD IN EXAMINATIONS. — The State Medical Examining Board has secured evidence that the questions to be submitted to applicants for license to practise have been surreptitiously obtained in advance. It is alleged that the trouble is in the office of the State printer, but the proofs have not yet been made public. The medical council is making a rigid examination of the matter.

MORTALITY FROM PULMONARY DISEASES. — The deaths from pulmonary tuberculosis in Philadelphia during 1899 amounted to 2,818 in a total of 23,796 deaths from all causes, or 11.8 per cent. Pneumonia is credited with 2,424 deaths.

A CENTENARIAN. — Mrs. Sarah Doran Terry has recently died in Philadelphia, at the ripe age of one hundred and eight. She was of Irish descent.

Miscellany.

SYMPATHY FOR CATS.

AN interesting incident is related in the *British Medical Journal*, of the late Dr. A. C. Stark, who was recently killed by an exploding shell at Ladysmith. Dr. Stark was an ornithologist of distinction who had volunteered for service as a civilian surgeon when the war broke out. His dying words were: "Take care of my cat." It appears that his fondness for cats was almost abnormal in its intensity. The correspondent who writes of him says: "Dr. Stark's fondness for cats is a point worthy of more detailed reference, and I am permitted by two of his brothers to give the following particulars: He had often told them that he was never able to concentrate his ideas satisfactorily unless a cat were in proximity to him; and I gathered from them that, although he always had a feline companion, his feeling was, in manhood, not so much for the individual specimen as of a want of one of the species about him. Accordingly, whenever he was engaged in his favorite study, that of ornithology — or in a game of chess, of which he was very fond — he liked to have 'puss' on his knee. As a boy, even when playing exercises on the piano, he always had a cat on his knee. As an ardent naturalist he was a lover of animals generally, but his particular favorites were cats and birds, and, though friendly with dogs, he did not care for one as a companion."

HUMIDITY AND DISEASE.

THE quantity of water vapor contained in the air varies, according to the *Medical Press*, within very wide limits according to the temperature and the direction of the prevailing winds. It is, however, not so much the absolute quantity of water vapor in the air that exerts an influence on health, as the proportion in relation to the saturation point of the air; in other words, it is the degree of interference with cutaneous and respiratory evaporation that is of importance. Sudden and extreme variations in the proportion of atmospheric humidity exert a well-marked influence on the absorption, transmission and reflection of heat, light and electricity, and these variations affect in a marked degree the activity of the vital processes. According to M. Chiais, the proportion of water vapor has a pathogenic influence whenever it falls below five or six grammes per cubic metre, or rises above 12 to 13 grammes. If the air contains less than five grammes the tendency is to diseases of the congestive type and the mortality returns are increased by maladies affecting chiefly the respiratory tract, though this circumstance acts prejudicially on sufferers from chronic cardiac disease and enhances the tendency to cerebral congestion, apoplexy, etc., in the aged. If, on the other hand, the air contains more than 14 grammes per cubic metre of water, the tendency is to inflammatory affections of the intestinal tract, gastro-enteritis and the like. There is reason to believe that it is less the relative abundance of water vapor that tells than the occurrence of sudden variations, these variations placing the organism at a disadvantage, only the physiologically active being able to adapt themselves to the change.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, JANUARY 13, 1900.

CITIES	Estimated population.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from				
				Infectious diseases.	Acute lung diseases.	Typhoid fever.	Diphtheria and croup.	Measles.

Deaths reported 2,393; under five years of age 721; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping-cough, erysipelas and fevers) 486, acute lung diseases 695, consumption

250, diphtheria and croup 98, measles 38, typhoid fever 31, whooping-cough 16, diarrheal diseases 15, scarlet fever 14, erysipelas 8, cerebrospinal meningitis 7.

From whooping-cough New York 13, Providence, Lawrence and Chelsea 1 each. From diarrheal diseases New York 5, Baltimore 4, Springfield 2, Washington, Nashville and Clinton 1 each. From scarlet fever New York 6, Boston 5, Baltimore, Cambridge and New Bedford 1 each. From erysipelas New York 6, Boston and Providence 1 each. From cerebrospinal meningitis New York and Worcester 2 each, Boston, Baltimore and Washington 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,404,408, for the week ending January 6th, the death-rate was 30.9. Deaths reported 6,870: acute diseases of the respiratory organs (London) 1,221, measles 156, diphtheria 121, whooping-cough 93, fever 55, scarlet fever 40, diarrhea 34.

The death-rates ranged from 44.9 in Brighton to 12.5 in Burnley: Birmingham 27.0, Bradford 24.7, Croydon 40.5, Gateshead 17.6, Hull 22.7, Leeds 25.6, Liverpool 34.4, London 37.1, Manchester 23.8, Newcastle-on-Tyne 26.3, Nottingham 40.8, Portsmouth 32.6, Sheffield 24.2.

METEOROLOGICAL RECORD

For the week ending January 13th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 20, 1900.

D. DICKINSON, medical director, ordered to duty as a member of the Naval Medical Examining Board, Washington Navy Yard, January 20th.

G. S. BEARDSLEY, medical director, detached from the Naval Retiring Board, Washington Navy Yard, and ordered home to await orders.

J. C. WISE, medical inspector, detached from the Naval Medical Examining Board, Washington Navy Yard, January 20th, and ordered to duty as member of the retiring board, same day.

L. G. HENEBERGER, surgeon, detached from the Naval Recruiting Rendezvous, Detroit, Mich., and ordered to the training station, Newport, R. I.

OLIVER DIEHL, surgeon, detached from the "Michigan" and ordered to the Naval Recruiting Rendezvous, Philadelphia, Pa.

A. R. ALFRED, passed assistant surgeon, detached from the New York Navy Yard and ordered to the "Texas."

F. W. OLCOTT, passed assistant surgeon, detached from the "Texas" and ordered to the Naval Recruiting Rendezvous, Detroit, Mich.

H. D. WILSON, passed assistant surgeon, ordered to duty on the "Michigan."

C. E. RIGGS, passed assistant surgeon, detached from the Naval Recruiting Rendezvous, New York, and ordered to the New York Navy Yard.

H. N. T. HARRIS, surgeon, ordered to temporary duty on the "Vermont" in connection with the crew of the "Albany."

R. SPEAR, assistant surgeon, detached from the Naval Recruiting Rendezvous, Philadelphia, Pa., and ordered to the "Constellation," temporarily.

H. A. DUNN, assistant surgeon, ordered to the Naval Proving Grounds, Indian Head, Md.

G. S. BEARDSLEY, medical director, placed on the list of retired officers of the navy from January 23, 1900.

J. M. FLINT, medical director, placed on the list of retired officers of the navy from February 7, 1900.

J. H. MCGUIGAN, pharmacist, detached from the Naval Proving Grounds, Indian Head, Md., and ordered to the New York Navy Yard.

S. ENGLANDER, pharmacist, detached from the Navy Yard, New York, and ordered to the Naval Hospital, New York.

(CHANGES BY CABLE FROM ASIATIC STATION).

D. L. WRIGHT, assistant surgeon, detached from the "Monterey" and ordered to the Isla du Luzon.

L. MORRIS, passed assistant surgeon, detached from the "Helena" and ordered to the "Brooklyn."

D. H. MORGAN, assistant surgeon, detached from the "Iris" and ordered home.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING JANUARY 18, 1900.

WERTENBAKER, C. P., passed assistant surgeon. To proceed to Greensboro, N. C., and Jessup, Ga., for special temporary duty. January 13, 1900.

LUMSDEN, L. L., assistant surgeon. Relieved from duty at Seattle, Wash., and directed to proceed to the San Francisco Quarantine Station and report to the medical officer in command for duty and assignment to quarters. January 16, 1900.

KING, W. W., assistant surgeon. To report to Surgeon L. L. WILLIAMS, Immigration Depot, New York, N. Y., for temporary duty, pending departure for Ponce, Puerto Rico. January 12, 1900.

THORNBURY, F. H., assistant surgeon. Relieved from duty at the San Francisco Quarantine and directed to proceed to San Francisco, Cal., and report to the medical officer in command for duty and assignment to quarters. January 18, 1900.

KAMUS, CARL, assistant surgeon. Relieved from duty at Havana, Cuba, and directed to proceed to Fort Stanton, N. M., and report to the medical officer in command, for duty and assignment to quarters. January 16, 1900.

STANSFIELD, H. A., assistant surgeon. Relieved from duty at San Francisco, Cal., and directed to proceed to Honolulu, Hawaii, and report to Surgeon D. A. CARMICHAEL for duty. January 17, 1900.

FOX, CARROLL, assistant surgeon. Relieved from duty at the Reedy Island Quarantine Station and directed to proceed to the Port Townsend Quarantine Station and report to the medical officer in command for duty. January 18, 1900.

TROTTER, F. E., assistant surgeon. Relieved from duty at the Tortugas Quarantine Station and directed to proceed to Havana, Cuba, and report to the quarantine officer for duty. January 16, 1900.

EDSON, E. R., assistant surgeon. Relieved from duty at St. Louis, Mo., and directed to proceed to the Reedy Island Quarantine Station and report to the medical officer in command for duty and assignment to quarters. January 17, 1900.

STEVENSON, JOHN W., acting assistant surgeon. Granted leave of absence for thirty days from January 22, 1900. January 17, 1900.

SOCIETY NOTICE.

MEDICAL SOCIETY OF THE STATE OF NEW YORK. — The ninety-fourth annual meeting of the Society will be held January 30 and 31, and February 1, 1900, in the City Hall, Albany, commencing at 9.15 A. M. on the 30th and ending at 1 P. M. on the 1st.

Communications relating to the presentation of papers or to any changes in the preliminary programme should be sent to the Business Committee: Wendell C. Phillips, Chairman, 350 Madison Ave., New York; Henry L. Elsner, Syracuse; Chauncey P. Biggs, Ithaca.

INFORMATION WANTED.

It is desired by the undersigned to investigate systematically the psychophysiology of anesthesia. For this purpose printed blanks have been prepared on which replies to certain simple questions may be written. All persons, and especially hospital surgeons, officers of medical societies and instructors in medical schools, are respectfully requested to send to the undersigned for as many of these as they care to distribute among individuals who have been under an anesthetic within a period not too long to prevent accurate recall of the facts. The blanks will be gratefully sent (and received when filled out) by George V. N. Dearborn, M.D., Physiological Laboratory, Harvard Medical School, Boston, Mass.

BOOKS AND PAMPHLETS RECEIVED.

The Diagnostic Value of Abdominal Palpation in Diseases of the Intestines. Carcinoma of the Duodenum. Hydrochloric Acid, Simple Method of Administering. By Charles D. Aaron, M.D., Detroit, Mich. Reprints. 1897-99.

INTESTINAL INDIGESTION, AND ITS RELATION TO PULMONARY DISEASE.

BY CHAUNCEY REA BURR, M.D. (HARV.), PH.B. (YALE),
Assistant Surgeon, United States Navy, Puget Sound Naval Station.

UNDER normal conditions, the small intestine is practically free from micro-organisms, while the large intestine is not. The immunity of the former and the susceptibility of the latter to infection appear to be due to the difference in the reaction of the contents of the respective intestines. The chyme is normally acid in reaction and so are the feces, but the intensity of the reaction is greater in the former than in the latter. The acidity depends first on the hydrochloric acid of the gastric juice, then upon the acids normally set free in the digestion of food, as lactic acid, acetic acid, etc., and finally upon the amido and bile acids. Most of these acids are liberated in the upper part of the small intestines and naturally give their reaction to the chyme in this situation; but as the mass moves onwards away from the seat of acid liberation, the continuous admixture with the alkaline secretions of the intestines and the formation of alkaline salts modify to some extent the degree of acidity.

Along with this modified reaction, it is to be remembered that peristalsis is less in the large than in the small intestine, that greater stagnation of the contents here occurs and hence a greater opportunity for bacterial growth. Such carbohydrates, fats and proteids as have reached this situation in their native state are digested and dissolved by bacterial enzymes; the whole effect being to supplement the pancreatic process. Some form sugar from starch, some peptone from proteid, while others break up fats. But the process does not necessarily stop here. The sugar may yield to lactic acid and alcohol; the peptone to amido-acids, as leucine and tyrosine, and the evil-smelling skatol, indol and phenol; the fats to valeric acid, butyric acid, etc. It appears that ptomaines cannot be elaborated in the presence of bile or of free oxygen osmosis, which normally occurs between the blood in the mucous membrane of the canal and the intestinal contents. They need not be reckoned with, therefore, in normal digestion. But toxins do occur and, along with the other products of proteid and carbohydrate digestion, are absorbed by the portal vein, and filtering through the liver diffuse into the general circulation as innocuous and nourishing substances. The work of the investigators who have proved all this is too recent and too well known to need more than passing allusion here.

The value of a healthy liver cannot be overestimated. It is a true filter, which arrests not only micro-organisms, but ptomaines, toxins and toxalbumins in small amounts.

It is evident from this brief summary of what occurs in normal digestion, that there are two points at either one of which, if a departure from the normal occurs, auto-intoxication may result. These two points are the intestinal tract and the liver.

If from any cause indigestion occurs in the former, the small intestine from being a practically sterile tube becomes a veritable culture tube for a variety of micro-organisms. No less than fifty different species have at different times been identified in the feces passed by patients suffering from intestinal indigestion and catarrh, and the list is constantly growing. These bacteria give rise to their own toxins, ptomaines and toxalbumins, which of course pass to the liver in the portal blood along with the proteoses and other imperfect products of gastric and intestinal digestion. The result is not difficult to imagine. The liver cells are poisoned; the filter leaks. The general circulation is flooded with a variety of poisons and auto-intoxication is established.

Again, it may happen, and often does, that a person is born with what is called an "insufficient" liver, that is, a liver which is functionally weak, which often breaks down and permits of undue leakage from the portal to the hepatic vein. Fothergill says that the children of town dwellers in the second and successive generations from those who immigrated to the city from the country are apt to be so afflicted. Or the insufficiency may result from syphilis or the abuse of alcohol and various drugs. Such an individual is more prone to infection from the intestinal tract than one who has a normal liver.

Having brought a suppositious patient to the point where his system is soaked with toxins, toxalbumins and, it may be, ptomaines, it is instructive to study him still farther, and observe (1) what efforts nature makes to eliminate the poisons, and (2) what symptoms arise in the process.

There are three avenues of exit through which the blood is wont to purify itself, namely, the skin, lungs and kidneys, and the vehicles in which the elimination is accomplished are the sweat, breath and urine. If the toxemia is intense enough any or all of the eliminating organs may show signs of distress. The skin may be hard and dry, pale, or of a sodden, muddy hue; or, again, it may be cyanotic, icteroid or bronzed. Erythema, urticaria, acne, eczema and psoriasis frequently develop. In the lungs congestion, edema or pneumonia occurs, while bronchitis is common. The kidneys are congested, or, it may be, in a state of acute parenchymatous degeneration. Where the toxemia is less intense but longer continued, the changes are more chronic in character and partake of the nature of round-cell infiltration, accompanied with arteritis and hyperplasia of connective tissue. Hence arise scleroses, atrophy and fatty degenerations.

There are few, if any, of the organs of the body which escape the effects of a general toxemia, but beside the excretory organs mentioned and the liver, which has broken down early in the process, the brunt of the toxic shock seems to be expended on the nervous system and the blood. Headache, backache, labored respiration and disturbed cardiac action are concomitants of every case of auto-intoxication and indeed of every case of toxemia. Organic change occurs in the nervous system if the irritation is continued long enough. As to the blood, a condition of hemoglobinemia develops; it clots with difficulty or not at all post mortem, and extravasations and hemorrhages are common.

It is to the pulmonary side of the picture that the writer wishes to draw particular attention. In intestinal indigestion thoracic oppression is frequently complained of. Of course, tympanitic distention of the intestines may in part account for this, but the same cannot be said of Cheyne-Stokes respiration and stertorous breathing when they occur, as they sometimes do. Again in *hepatis congestio* without tympanites the same difficulty in drawing a full breath is

complained of, and if the respiratory expansion is measured, it will frequently be found to have dropped from two and a half inches to one inch. This dyspnea occurs as well when the liver is not appreciably enlarged as when it is; and even when there is a mechanical impediment to the downward movement of the diaphragm, the thoracic breathing, which should be accentuated, is less than normal. As toxic principles are present in the blood in such cases, it is fair to assume that they are not without their own influence on the respiratory apparatus, particularly as the same oppressed breathing is seen in those cases in which a toxalbumin is known to be present in the circulation. Such cases are anthrax, hydrophobia, serpent bite and even exophthalmic goitre, as well as most of the infectious diseases. The medulla oblongata and the nerves issuing therefrom seem to be specifically poisoned by toxalbumins. One of these nerves is the pneumogastric, and it is to be noted that its deep origin is intimately associated with the respiratory centre. It is not without significance that so many of the toxemias are accompanied with a weak, hoarse voice. The laryngoscope reveals a condition of paresis of the glottis, and the larynx, as is well known, is supplied by branches of the pneumogastric nerve. In the early stages of phthisis, long before tubercular laryngitis occurs, there is a characteristic laryngoscopic picture. At the last meeting of the American Climatological Association, speaker after speaker rose up to testify as to the constancy with which this picture was observed.[1] Roe described it as anemia of the larynx, Ingalls as atrophy of the larynx, Langmaid as paresis of the glottis. The muscles and vessels stand out with unusual prominence through the pallid mucous membrane. However produced, there is but little doubt that the nerve supply is involved to a greater or less extent. Moreover, tuberculin, itself a toxalbumin, will produce this result, for Langmaid told how, in the early days of the tuberculin test, a number of his patients at the Massachusetts General Hospital were, unknown to him, treated with tuberculin, and it was the remarkable laryngoscopic picture which they subsequently presented which led him to ask for an explanation.

Evidence of a similar kind as to the respiratory insufficiency of incipient phthisis is afforded by Litten's diaphragm phenomenon[2] and thoracic x-ray examinations.[3] Only here it is a phrenic breakdown and not a pneumogastric which is proved. For both these observers have found that there is a shortened excursion of the diaphragm on the affected side, long before the B. tuberculosis can be demonstrated. Whether the inhibition occurs by way of the respiratory centre or is the result of a true phrenic neuritis does not appear. But the fact seems to be proved, as the writer some time ago pointed out,[4] that in pulmonary tuberculosis a paresis of both the phrenic and pneumogastric nerves occurs.

The truth of the matter seems to be that many toxalbumins as well as toxins and ptomaines, whether introduced by the venom of a snake-bite, the fangs of a mad dog, the excretions and secretions of bacteria, or the absorption of these, as well as of poisonous proteoses from the intestinal tract or elsewhere, may all embarrass the respiration. The downward excursion of the diaphragm is shortened, to say nothing of the lessened expansion of the thorax. Certain results must follow such a condition. The diaphragm acts as the piston of a syringe, filling the pulmonary capillaries with venous blood on its down stroke and emptying them on its up stroke. When its movement is interfered with, the capillaries are not emptied and a condition of stasis ensues. Under normal conditions the venous blood of the lungs is loaded with excrementitious principles. The aqueous extract of vapors exhaled by dogs has been found to cause death within twenty-four hours when injected into the veins of other animals. How much greater then is the danger in the static lung when these same principles remain for an indefinite period in contact with the walls of its fragile capillaries! One of the effects of such stasis is to weaken, if not paralyze, the epithelial cells of the pulmonary alveoli, and the endothelial cells of the capillaries, so that they no longer efficiently exercise their prerogative of phagocytosis. When the ciliated epithelium of the respiratory tract is in a condition of functional activity, it is inconceivable that either spores or bacilli drawn in with the inspired air can long remain in contact with the pulmonary epithelium; they are hustled out the way they came. But if for any reason this should not be the case, the epithelial cells of the pulmonary alveoli, or *macrophagi*, as Metschnikoff calls them, have still the power of killing and digesting them. It is only when these cells are poisoned or otherwise paralyzed that the power departs from them. The lungs are then open to microbic infection from without.

On the other hand, there is serious danger of microbic infection from within. Fraenkel reports a case[5] of a young man convalescing from typhoid fever, who in the fifth week after defervescence developed a new rise of temperature. An area of dulness was found posteriorly, and a needle thrust through the chest wall at this point drew off reddish pus. Later a serofibrinous exudate formed there. From both of these pure cultures of the typhoid bacillus were obtained. The facts seem to warrant the conclusion that the typhoid bacillus in this case made its way from an infected intestine, through a paretic liver into the general circulation, and thence to its final resting place and brood-oven in a pulmonary capillary. Even then the endothelial cells of the neighborhood might have exerted their phagocytic powers had they not been put to sleep by the same lethal dose which prostrated the epithelial cells of the pulmonary alveoli. So that without and within the lungs have been opened to infection.

The supposititious patient, therefore, who in the beginning was suffering simply from intestinal indigestion, has been brought to such a pass by the absorption from his intestinal tract of poisonous proteoses and ptomaines, that microbic infection of the lungs has not only been rendered possible, but has actually occurred. It is unnecessary at this stage of the investigation to limit the attention to any particular bacterium, for the least that any of the pathogenic variety can do is to initiate inflammation, and the most, to produce coagulation necrosis.

With the establishment of pulmonary foci of infection, the bacteria get to work, and the structural alterations of tissue which ensue are the same here as else

where. There is first diapedesis of the leucocytes and a leakage into the tissues of highly albuminous plasma, which from the presence of so many leucocytes has an inherent tendency to clot. The wandering cells of the connective tissue hurry to the support of the leucocytes and soon the "battle of the cells" is on. Exudation continues and the pressure in the infected area increases, so that this alone may result in much cellular death. The excreta of the bacteria — ptomaines, toxins, etc. — combined with this pressure is enough to account for the appearance of coagulation necrosis, which of course means cellular death in the tissue cells of the part. By means of proteolytic enzymes, which all bacteria capable of inducing inflammation seem to secrete, the necrosed area is digested and dissolved and pus is, in consequence, formed.

From the fact that coagulation necrosis in croupous pneumonia is limited to the epithelial lining of the alveoli, it would appear that in this disease, the primary infection occurs in the epithelial cells, that is, the bacteria are inhaled. The clotted exudate lies in the alveoli and thus produces less pressure than if it were beneath the surface.

For the same reason, the coagulation necrosis of pulmonary tuberculosis argues for a different avenue of infection. Here it is the capillary network of the lung which is attached. The exudate occurs outside the alveoli, and consequently the pressure is greater and coagulation necrosis possible. The bacteria therefore are brought to the capillaries by way of the general circulation, and in many instances are undoubtedly to be sought for in an infected intestine.

Buchner[6] demonstrated in 1890 that the serum of healthy blood has a germicidal action of its own. As a result of his investigations he concluded that the active element in this phenomenon is a living albumin, an essential constituent of which is sodium chloride, and which, when robbed of this salt either by dialysis or dilution, becomes inert in its behavior toward bacteria.

In pneumonia, as is well known, the chlorides disappear from the urine, and are locked up in the pneumonic exudate. Here they remain till resolution occurs. It can scarcely be doubted, therefore, that they perform a use, and probably a vital one, as in inflammations elsewhere the same paucity of chlorides in the urine is observed. It is to be noted also that with the reappearance of the urinary chlorides peptones appear as well. The digestion of the pneumonic exudate has preceded the peptonuria, and it may well be that sodium chloride has in some way assisted the peptonizing process.

With these facts before one, it would seem as if some changes might be made to advantage in the traditional treatment of pneumonia and pulmonary tuberculosis. In all cases of pulmonary congestion and inflammation the greatest care should be given to the condition of the digestive tract. The intestines should not only be evacuated and disinfected, but should be encouraged to resume their normal functions of digestion and absorption. For this purpose intestinal alteratives are indicated, and of these none stand the test of use better than calomel and podophyllin. Albers states that while many bacteria in the intestinal contents are readily passed in the stools, others remain behind in the intestinal glands and follicles, where being protected by a film of mucus, they cannot be reached by ordinary intestinal antiseptics. Yet these are the bacteria which are the first to give up for absorption their chemical products and which it is the most desirable to destroy.[7] Small and repeated doses of these substances after the manner used in the Woodbridge treatment of typhoid fever fulfil these indications. Three, four or five movements of the bowels per diem in pneumonia will tend to do more good than harm. The addition of such drugs as salol, carbolic acid, salicylic acid, menthol, thymol, etc. is of doubtful benefit. For whereas they disinfect the contents of the intestines, many of them are soluble, and once absorbed have a toxic power of their own, and depress the heart in particular. Under such treatment, if judiciously applied, the intestines and liver resume their functions. An adjunct of great value is the inhalation or ingestion of oxygen. It will be remembered that where oxygen osmosis occurs, the formation of ptomaines seems to be prevented and this is as true of the vessels in the intestines as in the lungs. Again the use of calomel and podophyllin, by stimulating the liver and its urea-excreting function, acts upon the kidneys, and diuresis is encouraged. Thus the blood unloads itself of excrementitious matters. The wet pack is useful for the same reason.

In pneumonia two stages should be distinctly recognized, as indeed they generally are. In the first stage there is hyperemia of the pulmonary capillaries, diapedesis of the leucocytes and the exudation into the pulmonary alveoli of a viscid, albuminous plasma. Obviously much good could now be done if an astringent could be employed which had the power of contracting the pulmonary capillaries and so aborting the process. The soluble phosphate of iron has this power if used in small and repeated doses, and the addition of tincture of aconite seems to increase its powers. The writer has repeatedly aborted the pneumonic process at this stage and by this means alone after the previous administration of a purge. It is otherwise, however, when hepatization has occurred. The path to recovery here lies through resolution or the digestion of the pneumonic exudate. The process can be hastened to some extent by the administration of sodium chloride and pancreatin. The ideal way to administer this is to add a few grains of pancreatin to a pint of normal salt solution and inject it well up into the sigmoid flexure.

The recent work of Krönig and Paul[8] throws some light on the way in which sodium chloride acts in septic blood states. It seems that when salts are dissolved in water, they undergo an electrolytic dissociation into metallic and acidic *ions*, the former being the electropositive *cation*, the latter the electronegative *anion*; sodium chloride, for example, resolving itself into its sodium, or *metal-ion*, and its chlorine, or *acidic-ion*. The germicidal value of a metallic salt depends not only upon its specific character, but also upon that of its *anion*, which in the case of sodium chloride is chlorine. Solutions of sodium chloride, therefore, entering the circulation, are dissociated into sodium and chlorine, of which the sodium unites with the carbon dioxide present to form sodium carbonate and bicarbonate and thus assist in maintaining the alkalinity of the blood, while the chlorine unites with the bacteria themselves or with any free hydrogen present to form hydrochloric acid and in

either event exerts an antiseptic influence at the seat of inflammation.

Bovee says[9] the presence of sodium chloride in the blood favors osmosis and retards coagulation. These of course are desirable effects in the first stage of pneumonia, but he also warns us that the salt if present in excess gives rise to pulmonary edema, dyspnea, headache, vertigo, mental excitement or delirium and severe pain in the left side.

The pancreatin is added in the hope that it may assist in the digestion of the pulmonary exudate, and in the conversion of any primary or secondary proteoses that may be present into peptones. These proteoses result not only from imperfect proteid digestion in the alimentary tract, but from the action of bacterial enzymes on the necrosed tissues of the infected part. Both proteoses and peptones are toxic if free in the circulation, but the diffusibility of the latter is much greater than the former and hence it happens that peptones will leave the blood in the urine, while proteoses remain behind.

Lolu and Emmerich have shown[10] that the enzymes of certain diseases kill not only their parent germs, but also those of cholera, typhoid fever, anthrax, diphtheria, black plague, staphylococci and, probably, gonococci. The bacillus of tuberculosis seems incapable of producing an enzyme that is fatal to itself. This is also true of black plague, and for this reason, say these investigators, the antitoxin of black plague has failed to cure. This hint should not be lost, and it is earnestly to be desired that experiments should be instituted as to the effect of pancreatin on the growth of the bacillus tuberculosis.

Fresh air and the cure of intestinal indigestion will do much to improve the condition of those suffering from pulmonary tuberculosis, and, if begun early enough, a cure may be looked for in a certain proportion of cases. The use of normal salt solution is also to be recommended.

The writer can never forget the extraordinary improvement which once followed his use of a sodium-chloride solution in a case of this kind. The patient was far gone in consumption and had been under observation for many months. One morning the word came that he was dying, and on arrival at the bedside it seemed indeed as if dissolution were at hand. There was great dyspnea, the face was pale and bathed in a cold sweat, the pupils were dilated, the pulse fluttering and almost imperceptible and the temperature 101° F. About three grains of sodium chloride were dissolved in a teaspoonful of boiled water and this was injected under the skin. In a few moments it seemed as if the breathing were easier. At the end of half an hour there was no doubt of it, and in addition the pallor and cold sweat had gone; the pupils were normal in size, the pulse was regular and perceptible and the temperature had dropped from 101° to 100° F.

This patient lived some months longer, but never again had such an attack, and the breathing was comparatively free to the end. The daily use of salted milk or beer had probably much to do with this.

BEQUEST TO A HOSPITAL. — The Flower Hospital, New York, has recently received $200,000 from the family of the late Roswell P. Flower.

CASES OF CHOLECYSTOTOMY.

BY EDGAR GARCEAU, M.D., BOSTON,
Surgeon to Out-Patients in the Free Hospital for Women, and in St. Elizabeth's Hospital, Boston.

CASE I. The patient was a married woman, thirty-eight years old, who had never been pregnant. She had always enjoyed good health except during the two years previous to her operation. During this time she had complained of some indigestion and occasional cramps in the region of the epigastrium, which lasted a few minutes at a time; but there had never been any severe attack of colic like the one from which she was suffering when first seen. The history of the attack was that of a sudden sharp pain localized in the region of the epigastrium and also felt in the right hypochondrium just below the ribs. It was penetrating, knife-like, and extended to the right iliac region. There was also slight jaundice, as evidenced by the color of the skin and the bile found in the urine. She was quite prostrated and confined to her bed.

A catheterized specimen of urine showed four per cent. of urea, a few leucocytes, a little blood and a few small granular casts. On examination of the patient, resistance and tenderness were found over the gall-bladder, and likewise over McBurney's point, but no tumor was felt. The temperature was 101° F.

She was treated palliatively for a short while until the pain and tenderness had subsided, and when this happened the operation was performed. The diagnosis of biliary calculi seemed probable, but that appendicitis also did not exist could not be asserted. The incision was therefore made midway between the ribs and Poupart's ligament in order to allow of an examination of the appendix. It was found that the appendix was the seat of inflammation and it was removed. The incision was now extended upwards toward the ribs and the gall-bladder exposed. It was contracted and small. In it was a little thick, brownish fluid and fifteen calculi of various sizes. After removing these, the open gall-bladder was sewed to the upper end of the incision and a drain inserted. One stone was left in the bottom of the gall-bladder, as it could not be easily removed. No forcible attempts were made to remove it on account of the fear of hemorrhage, so serious in these cases. The gall-bladder was washed out twice daily after the operation, but the stone never appeared; it probably still remains in the gall-bladder, or has been passed through the cystic duct, in which it seemed to be firmly impacted.

The patient rallied well after the operation. The fistula closed in about three weeks, during which time bile was discharged in varying quantity, never in very large amount. When last seen, in November, 1899, ten months after operation, she was well, with the exception that occasionally she had had some slight pain in the right lumbar region which radiated to the front, but it had never been severe and she considered herself cured. The general health was excellent and all the bodily functions were acting properly.

A recurrence of symptoms must be looked for in this case, it is feared. The co-existence of appendicitis is interesting, and when it is remembered that the pain in appendicitis may be felt in almost any part of the abdomen, there was ground for believing that the case might well have been one of appendicitis with catarrhal jaundice. Before the incision was made there was doubt as to whether the operation

was to be for appendicitis or for removal of biliary calculi. If there had been a tumor in the region of the gall-bladder the diagnosis would have been more certain with reference to the gall-bladder. Localized tenderness over both gall-bladder and appendix was the deciding physical sign which called for exploration of both.

Case II. The patient was a married woman, forty-eight years old, who had been suffering from symptoms of indigestion for a period of twelve months before her operation. There had been a gradual decline in the general health and strength and she was finally reduced to a condition of extreme emaciation and weakness. Intense jaundice, the onset of which had been gradual, had been present during six months. The stools were clay-colored. Occasional pain of mild severity was complained of in the *left hypochondriac region*, just to the left of the stomach, and there never had been any distress or pain in the *region of the gall-bladder*. There had been no vomiting and there was no history of biliary colic. Examination was entirely negative, with the exception that there was some tenderness on pressure over the stomach in the epigastric region. The gall-bladder was not distended and pressure over it elicited no tenderness, nor even resistance of the abdominal muscles. No tumor could be felt anywhere.

The case when first seen, in June, 1899, was looked upon as one of carcinoma of the stomach with secondary invasion of the liver, and an unfavorable prognosis was given. But during the summer the patient gained five pounds. This improvement, considered with the atypical group of symptoms, suggested that an exploratory incision be made, in the hope that the jaundice might be caused by remediable calculous obstruction of the bile-ducts. In any event a positive diagnosis could be made by opening the abdomen.

The operation was performed in September, 1899. A crucial incision was made below the tenth rib, exposing the gall-bladder. It was small and firmly adherent by its upper surface throughout its whole length to the under surface of the liver. A small amount of yellow, glairy fluid was aspirated from it; after incising it, six calculi from two to three centimetres in diameter were removed with a pair of dressing forceps. There was some hemorrhage while removing these small stones, but it was not considerable. The finger discovered another stone in the bottom of the gall-bladder, but it could not be dislodged. Rather forcible effort was made with the forceps to remove it, when an abundant venous hemorrhage occurred. The gall-bladder was at once firmly packed with gauze, which controlled the hemorrhage, and the incised sac was sewed to the upper angle of the incision; the lower part of it, however, could not be approximated to the peritoneum on account of the tenseness of the abdominal walls. A gauze packing was therefore placed in front of the gall-bladder to serve as a drain, and the rest of the incision closed. She rallied well under stimulants and an hour after she was put to bed, the pulse was 75 and of good strength. In the evening the pulse failed suddenly and she rapidly died.

At the autopsy the abdominal cavity was found filled with blood clots. The blood had escaped from the gall-bladder, spilling over the edge of it into the peritoneal cavity. The liver, stomach, pancreas and duodenum were removed from the body in one mass and a careful dissection made. The hemorrhage was found to have proceeded from the very vascular walls of the gall-bladder. A very large stone weighing 130 grains was found at the bottom of the gall-bladder. It measured one and one-fourth inches in length and an inch in width.

The relations of the gall-bladder and the ducts were as follows: The common duct divided at the usual point. The left hepatic duct went to the left lobe of the liver in the normal way. The right hepatic duct was one and one-half inches long, and entered at once into a cavity formed by the lower part of the gall-bladder, in which lay the stone; there was no cystic duct whatever, and on the upper surface of the cavity were several biliary canals entering directly into the substance of the liver. It is possible that the stone in its passage downwards dilated the cystic duct and also the upper part of the right hepatic duct in such a way that both were transformed into a single cavity; subsequent inflammatory changes may have caused adhesions between the upper part of the thus newly-formed sac and the under surface of the liver. There was a constriction about the end of the stone facing the gall-bladder which prevented its extraction, and there was also a vascular band running from side to side of the gall-bladder directly over the stone and further rendering extraction a difficult if not an impossible matter. To have cut this band would have meant a serious hemorrhage. To have excised the gall-bladder in the usual way was impossible as there was no pedicle. To have cut it out would have also meant serious hemorrhage, and sewing the edges together would have been, in this case, a most difficult matter, and in the reduced state of health of the patient, unwarranted. It is possible that the hemorrhage might have been better controlled by sewing up the incision in the gall-bladder. This would have meant a subsequent operation at the end of a few days, when, however, the same conditions would have been encountered. One other method was open to trial for removal of the stone in case hemorrhage had not been met with. It would be possible, in a similar case, to split the gall-bladder down to the common duct, and so remove a stone; but in this case it probably would have given rise to much more serious hemorrhage than that which occurred, owing to the extreme vascularity of the walls.

Case III. The patient was a man of vigorous constitution, seventy-two years of age. He was of short stature, but thick-set and strong. His health had always been good with the exception of attacks of biliary colic, which had come at frequent intervals during several years preceding his operation. During these attacks pain in the right hypochondriac region was severe, and he usually had to take to his bed. Jaundice, during the attacks, was inconstant. There was indigestion at times, but except for this his general health was excellent, and he was able to work at his trade, that of shoemaking, without interruption. During his last attack of colic the pain was very severe, confined to the region of the gall-bladder, and very prostrating. Large doses of morphia were required to control it. Jaundice was marked and the stools were clay-colored. There was no tumor.

The operation was performed on September 20, 1897. A triangular incision was made over the gall-bladder and that organ exposed. It was found moderately distended with normal bile, but there was no

stone in it. Examination of the ducts with the forefinger revealed a hard mass in the region of the head of the pancreas. An attempt was made to explore it further with the hope of removing it, but at this point of the operation breathing became somewhat embarrassed and the pulse flagged. Added to this was the difficulty of performing an operation of this nature on an old man with thick abdominal walls. It was therefore thought advisable to make an anastomosis between the gall-bladder and the transverse colon. This was quickly done with the Murphy button, the smallest-sized one being used. The button was passed on the fourteenth day. Convalescence was complicated by a severe attack of catarrhal pneumonia affecting the right lung, and the patient nearly died from the effects of this and the shock of the operation. He finally recovered, however, without further accident.

He was last seen in November, 1899, two years after the operation. His health was perfect. He had never had a pain since the operation. Digestion was good and in every way he was in a normal condition.

The case illustrates the great value of the Murphy button in an emergency of the nature described. The time consumed in adjusting the button was very short, and the result good. It is a question whether the stone has since been passed or whether the artificial passage between the gall-bladder and the large intestine is still serving as a passage for the bile.

SOME POINTS SUGGESTED BY THE CLINICAL STUDY IN ONE HUNDRED AND EIGHTY-SIX CASES OF VALVULAR HEART DISEASE.[1]

BY RICHARD C. CABOT, M.D., BOSTON,
Physician to Out-Patients, Massachusetts General Hospital.

I. METHOD OF RECORDING.

ANY one who tries to record statistically a considerable number of cases of any one disease soon meets the following difficulty: Almost any form of chart in which the symptoms are arranged up and down and the patient's numbers across the top (or *vice versa*) soon grows so large as to be unmanageable; the eye grows confused in following the columns, and mistakes easily occur. It is also difficult to get a satisfactory material such as will resist wear and tear.

In recording the cases of which my paper of to-night is a study I have used a book in which points regarding etiology, symptomatology and physical signs are written in a column at the left margin of the first sheet of the book. Then all the other sheets in the book are cut off along their free margin to such an extent that as each fresh page is turned over for the recording of additional cases, it comes in close juxtaposition to without covering the printed column of data in regard to which we are collecting statistics. In this way a series of cases, even up to several hundred, can be recorded in a single book without any of the inconvenience which soon meets us with any form of chart with which I am acquainted, as soon as we get beyond 30 or 40 cases. To record any given point in regard to etiology, symptoms or signs, we need with this book only so much time as is required to make a plus sign or a zero mark opposite the proper word in the printed column which is always visible and close at hand, owing to the arrangement of the book. I usually stamp a diagram of the front and back of the chest into each record and draw out the areas of the murmurs heard, marking their seat of maximum intensity, as well as the area of the heart.

[1] Read at a meeting of the Boston Society for Medical Improvement, November 20, 1899.

II. THE APEX BEAT.

(*a*) When we speak of localizing the apex beat of the heart in order to ascertain the size of the organ, what do we mean, and what ought we to mean? It is well known that it is not the apex of the heart which gives rise to the so-called "apex beat," or cardiac impulse. The impulse is caused by a portion of the right ventricle. In localizing the maximum impulse, therefore, we are not localizing the apex of the heart. What then *shall* we look for? It has been my practice to give the name of "apex beat" to that portion of the chest wall farthest to the left and farthest down at which any rise and fall synchronous with the heart beat can be felt. This is often some distance outside of the *maximum impulse*, and it might easily be objected that what we are localizing by the method here suggested may be simply the outer limit of a *wave* transmitted to the chest wall by the heart. In deciding this question, the evidence of percussion seems to me of great value, and it has been my uniform experience that the percussion dulness begins not at the point where the maximum cardiac impulse is to be seen and felt, but some distance farther out towards the left axilla and farther down towards the base of the chest, in a position corresponding to the lowest and outermost point at which *any* pulsation even very faint, can be felt.

(*b*) In defining the apex beat, one should be careful so to frame his definition as to include those cases (not at all infrequent in my experience) in which we have a systolic *retraction* at the apex instead of a systolic *impulse*; for I need not remind you that the presence of a systolic retraction at the apex is in no way diagnostic of pericardial adhesion, but is often due simply to the negative pressure produced within the chest by the powerful contractions of a hypertrophied heart.

III. THE PLACE OF MAXIMUM INTENSITY FOR AORTIC REGURGITANT MURMURS.

Modern text-books on diseases of the heart and on physical diagnosis are beginning to correct the old misstatements handed down through many of the older books regarding the point at which the aortic regurgitant murmurs are best heard; yet in the "Twentieth Century Practice of Medicine," Whittaker stated in 1895 (Vol. IV, p. 251), "The murmur is heard in greatest intensity in the second interspace to the right of the sternum."

Musser, in his "Medical Diagnosis," page 382, gives three positions, at any one of which the murmur of the aortic regurgitation may be at its maximum. One of these is in the second right interspace and two are in the middle line of the sternum, at different levels. On page 380, he says, "When a murmur is heard with greatest intensity in the second right interspace, it is usually generated at the aortic orifice." On page 429, he admits that "in some instances, the maximum of intensity is greatest at the fourth left costal cartilage, or even at the apex."

Tyson, in his "Physical Diagnosis," page 136, says, "It is sometimes loudest in the aortic area but often

over the mid-sternum, and it is even well heard as low as the ensiform cartilage or at the apex itself."

Osler, in the last edition of his "Practice," page 713, says, "On auscultation, there is heard a murmur, during diastole, in the second right interspace, which is propagated with intensity towards the ensiform cartilage, or down the left margin of the sternum towards the apex."

These statements are a considerable improvement over those of the older text-books, in which the occurrence of aortic murmurs with maximum to the left of the sternum is hardly mentioned, but I do not think that even the statements just quoted give a true idea of the facts, for they seem to suggest that the right side of the sternum is the *common* place to hear the murmur best, and the left side the *rarer* place. In 44 cases which I have carefully examined this summer with reference to this point the murmur was best heard to the left of the sternum in 36; best heard to the right of the sternum in four cases; in the centre of the sternum in two cases; while in two more there were two areas of equal intensity, one at the right and one at the left of the sternum; while over the sternum itself, the murmur was very feeble. In this series, which I believe to be a typical one, the murmur was best heard to the right of the sternum in only four out of 44 cases, or less than one-tenth.

IV.

My fourth point I want to put simply in the form of a question: Upon what evidence should we base the diagnosis of aortic stenosis? Knowing, as we do, that a loud systolic murmur in the traditional aortic area may be produced by simple roughening of the aortic valves or the aorta itself, without any genuine stenosis, and that this murmur may be propagated into the great vessels, what positive signs have we for distinguishing aortic roughening from aortic stenosis? Is the presence of a tactile thrill, in addition to the signs just mentioned, sufficient to warrant in making the diagnosis of mitral stenosis, or do we need in addition the *pulsus tardus, rarus, parvus* of the classic descriptions?

V. RELATIONS BETWEEN THE VALVE LESIONS AND HYPERTROPHY.

The study of the 186 cases of this series has given me, I think, reason to deny that there is any one form of valve lesion which is constantly associated with the clinical evidence either of hypertrophy or of the lack of hypertrophy of either ventricle. The classical text-book statements, that in pure mitral stenosis we have no hypertrophy of the left ventricle; that in mitral regurgitation evidence of a predominant or exclusive enlargement of the right ventricle can be made out; that in aortic regurgitation the left ventricle must be enlarged, all these seem to me contrary to the facts of observation. I have seen several cases of well-marked aortic regurgitation without any evidence of hypertrophy of the left ventricle, and several of apparently pure mitral stenosis in which there was every reason to suppose that the left ventricle was enlarged, while in a majority of cases of mitral regurgitation such enlargement of the heart as could be demonstrated seemed to affect the left ventricle rather than the right. In connection with this, I would like to call attention to the worthlessness of epigastric pulsation as evidence of hypertrophy of the right ventricle. Surely we have all seen it present when the heart was normal, both during life and at autopsy, and, on the other hand, seen convincing evidence of hypertrophy of the right ventricle without any epigastric pulsation.

VI. PRESYSTOLIC MURMURS IN CONNECTION WITH AORTIC REGURGITATION.

It is a well-known fact, first described by Austin Flint in 1862, that we may have every physical sign of mitral stenosis, and yet at autopsy find the mitral valve normal in cases where there is an associated regurgitation through the aortic valve. I mention this fact simply to call attention to two points: (*a*) First, that unless we always have it in mind and are closely on the lookout for it, we may altogether overlook the aortic lesion. In certain cases the diastolic murmur is very faint and the presystolic roll and thrill at the apex impress themselves upon one's mind to the exclusion of everything else. The importance of not making this mistake, that is, the importance of recognizing a faint diastolic murmur in the presence of a loud presystolic roll and thrill, is that the prognosis of a combined lesion of both the aortic and mitral valves gives a much worse prognosis than a lesion of the mitral valve alone. (*b*) Second, I want to ask if any one here present can tell me whether it is ever justifiable to make a diagnosis of mitral stenosis in a case where *we are sure there is aortic regurgitation*. Is there any way, in such a case, in which we can tell the Austin Flint murmur from the murmur due to organic changes in the mitral valve?

EPILEPSY.[1]

BY WALTER E. PAUL, M.D., BOSTON,
Assistant Physician in Diseases of the Nervous System, Massachusetts General Hospital.

The symptom complex of epilepsy falls within the experience of every physician, and the diagnosis, prognosis and treatment of this affection are most important from the practical standpoint. The class of cases here considered belongs to so-called idiopathic epilepsy, and not to the cases in which the convulsive attacks are symptomatic. For although in many cases of epilepsy pathological cerebral changes have been found, by no means is there associated with epilepsy any constant pathology. Further study of epilepsy may demonstrate a uniform etiology, but if due principally to a disordered function of conducting paths, the etiology would vary widely in individual cases, and might well be beyond discovery. Féré[2] says of epilepsy, that "the most varied causes produce the same clinical phenomena."

In a general way it seems unlikely that a special toxin or class of toxins is solely, or even in large measure, the one factor causing epileptic seizures. It is reasonable to grant that all of the human kind elaborate the same chemical substances in the economy and that the central nervous system of every individual is subjected to practically the same metabolic processes and products. But there is a wide variation in neural endowment. Is not the cause of epilepsy almost absolutely in the machinery of the brain and cord — a vice of the nerve tissues, a limited

[1] Read at a meeting of the Boston Society for Medical Improvement, November 20, 1899.
[2] Féré: Twentieth Century Practice, vol. x, p. 586.

capacity to meet all nerve stimuli and retain normal nerve equilibrium? From this point of view every nerve reaction that occurs in the life of an epileptic bears a relation to the culminating symptom of the fit. It is not simply the influence of leucomaines, but other events in the bodily and intellectual life are contributing mites, some against, but more for, the developing attack.

In epileptiform fits that are symptomatic of gross lesions there is a variety of specially prominent factors, as, for example, in cases due to syphilis, or the presence of a foreign body in the brain, or tumor, or alcohol. It is worthy of remark that Gowers[3] inclines to the opinion, though he does not dogmatically state it, that convulsive attacks in a syphilitic are not attributable to the virus in the blood but to a lesion of nerve tissues. This probability is reinforced when we remember the comparative rarity of convulsions in syphilitics. Therefore, in idiopathic epilepsy the autotoxic theory seems to me to occupy a small place in the etiology.

Diagnosis. — The diagnosis of epilepsy is simple in many cases, but in the milder attacks it may require much study and observation to determine the character of the symptoms. For some time the mildest attacks may pass unrecognized; in which, for example, one pauses a moment in whatever he is doing, ceases speaking, or drops some object from the hand, or has a transitory giddiness. Night attacks may be discovered only by accident, and Trousseau records a case in which the first knowledge of nocturnal epilepsy was brought to light by a dislocation of the shoulder. The principal difficulty in diagnosis is to differentiate between epilepsy and hysterical convulsions, and it may be impossible to determine from the history whether only one is present or both, for hysteria may be superimposed on true epilepsy. When there is doubt it is perhaps unwise to rule out epilepsy even on the apparently typical hysterical character of an individual fit. The subsequent and previous attacks might well be epileptic, yet the patient's observation and that of his family and friends would regard all attacks of the same character. If the attack is of abrupt onset, and there is loss of consciousness, if the tongue, lips or cheeks are bitten, or there is some escape of saliva, even a slight drooling, and the urine is passed in the attack, and if these symptoms are followed by a period of stupor or confusion of thought, then a positive diagnosis of epilepsy is established. The occurrence of some bodily injury is strong corroborative evidence of true epilepsy, be it a burn, a cut or a broken bone. Even without a clear, assured history of an epileptic fit, it is wise in directing treatment to regard the patient as a probable epileptic rather than as simply hysterical. Amelioration under treatment would only strengthen the suspicion of epilepsy.

So-called psychic epilepsy presents an unusual variety of the disease. Motor symptoms are replaced by impulses and ideas that may impel the individual to various acts. No memory of these is retained. The defence in murder trials not infrequently resorts to this explanation of the homicide.

Prognosis. — Prognosis deals with grand mal and petit mal cases. Perhaps the three following are the most important considerations: (1) What can be expected from treatment? (2) How does the existence of epilepsy affect longevity? (3) What is the future of an epileptic in his relation to society and the state?

According to the statistics, a large proportion, 80 to 90 per cent., of epileptics are helped by treatment. The attacks are lessened both in severity and frequency, and in favorable cases cease for long periods.

As to cure, I quote Dr. Edgar J. Spratling:[4] "A very small percentage do recover; but a new onset of the disease is a fate hanging immediately over every former sufferer. Simply because a man goes an indefinite period without a convulsion should not induce us to state epilepsy with him in the future is impossible or even improbable." It seems justifiable to hold out to a patient the expectation of improvement.

The influence of epilepsy on life is in most textbooks referred to as of small moment. Dr. Worcester,[5] of Danvers, has demonstrated that in asylums for the insane epilepsy in its severe forms is a deadly disease, with a mortality of 19.23 per cent. due directly to the disease.

The development of rapidly-recurring convulsions, the status epilepticus, is cause for gravest apprehension. At any moment, however, the attacks may cease, and the patient recover.

The relation of an epileptic to society and the state is by no mean a simple problem. Few occupations are especially fitted for epileptics; few employers welcome the epileptic employé. An attempt to secure work for one of the afflicted is often discouraging, and if the fact that one is epileptic is discovered after being engaged as a workman, the employer feels he has been deceived. It is easy to see how society is steadily forcing an epileptic into the discouraged and shiftless class. Thus the epileptic condition may be aggravated and the individual finally become a ward of the state.

Treatment. — To the treatment of epilepsy a great deal of study has been devoted. Few diseases have had more drugs and measures directed to amelioration or cure; and epileptics are attracted in large numbers by quacks. Original methods and schemes of treatment have been proclaimed by enthusiasts, but no panacea is yet known. In spite of all the discouragements to a positive cure a great deal is being done for the amelioration of epilepsy.

Treatment includes hygiene, diet, palliative measures, drugs, surgical measures and hospital life. I have reviewed the treatment of the cases coming to the Out-Patient Department of the Massachusetts General Hospital for 1896, and the results are embodied in what follows. Each patient is ordered to take a daily sponge bath, observe regular habits, avoid excesses and vices, and take sufficient exercise out of doors. Caution as to occupation was given in a few cases, for in most epileptics risks have to be taken and excessive caution is to be avoided. Meat is uniformly prohibited hospital patients, but eggs, fish and milk are allowed and urged. These directions are insisted on for Thanksgiving and Christmas Days as well as others. Caution against overeating is given, and an attempt is made to maintain the health of the alimentary tract — a most important consideration, as an error in diet frequently precedes an attack. Refraction, phimosis, nasal obstructions and aural dis-

turbances receive special attention, with the hope of palliation but not the expectation of cure.

One chemical element, bromine, furnishes salts nearly unanimously adjudged most effective of all drugs in opposing the epileptic habit. Opinions vary as to the choice of a bromide salt. At the Massachusetts General Hospital the sodium salt is prescribed most frequently, with an initial dose of 20 grains three times daily for adults. It is sometimes combined with the potassium salt and the ammonium salt, and not infrequently the potassium bromide is used alone. The choice of a drug for treating epilepsy is a simple matter, but it requires a fine judgment to regulate the dosage and method of administering to attain the best results. Shall the twenty-four-hour amount of bromide be given in one dose or divided doses? In nocturnal epilepsy the drug is administered usually in one dose at bedtime. Shall the amount be varied on alternate days, or every third day, and so on? Shall the bromide be omitted for a time or the amount be increased or diminished? Variations along these lines are followed at the hospital. The skin eruptions are combated with potassium arsenitis, but bromide is not omitted because acne exists, even of severe degree. Two cases at the hospital received Flechsig's treatment under Dr. Putnam's direction. In one the attacks ceased for a year and were less frequent when they recurred. The other case was in no wise benefited. Flechsig's treatment has gained no permanent place and what value it has seems to be due to the bromide used.

Nothing is attempted with hospital patients in the way of inhibiting an impending attack. Unless an aura lasting some little time exists such efforts would be useless. A mother, in one hospital case, gives her epileptic child a shaking and thus inhibits the fit. A man reported that tapping his head was effective.

A recent addition to the bromide group is bromalin, a combination of bromide of ethyl and formin. Féré, finding other measures failed to relieve bromidism, and having recognized that constipation and flatulence were often present, surmised that bromidism might be the consequence of auto-intoxication. Large doses of beta-naphtol and bismuth salicylate were followed by striking results; the tremblings, rash and digestive disturbances disappeared; the appetite improved and there was a general sense of well being. Bromalin, invented by Bardet, meets the need of an antiseptic bromide preparation; and its use in a small number of cases by Rohrmann [6] has been followed by results similar to those obtained by Féré with beta-naphtol and bismuth salicylate. Merck advises giving bromalin in 30-grain doses in wafer paper from one to four times daily. Bromide of strontium is strongly advocated by observers who claim it to be non-toxic. A. Roche,[7] of Dublin, states that the strontium salt produces no constitutional symptoms and never, so far as he knows, caused a rash. The doses used were 60 to 180 grains daily.

A number of surgical experiments have been tried; ligation of the carotids or vertebrals, cutting of eye muscles, trephining and sympathectomy — each has had a certain vogue. Unless some strong, special indication exist, these measures have accomplished little or nothing towards cure or even help. One operator, Chipault, continues hopeful of benefits from sympathectomy; but others can discover no favorable results from removal of cervical sympathetic ganglia.

In the last five or six years institutional treatment of epilepsy has been inaugurated in several States; and the results of even a rather brief trial of this method of caring for epileptics are most encouraging. The cardinal measures carried out at the hospital, or colony, for epileptics, have to do with the diet, hygiene, out-of-door life, and, most important of all, systematized occupation. Very little bromide is used. Some of these institutions are filled to the limit of accommodation and have a waiting list of several hundred eager to be admitted. This method of dealing with epileptics has accomplished most gratifying results; and the special hospitals promise to add largely to the scientific knowledge of epilepsy. At present they offer the most acceptable means for the care of a large proportion of epileptics.

Clinical Department.

NOTES FROM THE NEUROLOGICAL DEPARTMENT OF THE MASSACHUSETTS GENERAL HOSPITAL.

I. Case of Combined Superior and Inferior Poliencephalitis.

by G. L. Walton, M.D., Boston.

The patient, a man fifty-three years of age, was seen in consultation with Dr. Aldrich, of Somerville, and consented to come to the hospital for further study and observation on account of the interest of his case. His occupation for the last fifteen years has been that of a die sinker, using tools similar to those of an engraver. There has been no wasting or weakness of the hands, and no other symptoms which could be attributed to his work excepting, perhaps, a slight paresthesia of the right hand.

The first cerebral symptom noted was indistinctness of speech, coming on suddenly the latter part of August, 1899, previous to which time he had been in good health. He found no difficulty in choosing words, but there was indistinctness of articulation. He had chewed gum at his work practically all the time for several months, and had thought this might have something to do with his trouble. One month later (the last of September) weakness in the movements of the lips appeared; at about the same time he found it hard to masticate on account of muscular weakness; food would catch in his cheek, and he began to drool, particularly while eating. At this time he could not whistle, and all the movements of the tongue were greatly impaired; the face is said to have been drawn to one side. Some time in October he noticed a drooping of the right eyelid, a symptom which had appeared a year previously, but was transient and unaccompanied by diplopia. With the present attack diplopia appeared and has persisted. In November he complained of pain in the back of the neck, appearing only when he was out and about (ocular?). There has been some trouble in swallowing, affecting apparently the constrictor rather than the laryngeal muscles, as the difficulty was in pushing along solid food, but there was no choking. He was unable to eat solid food at all during December on account of inability to masticate. There has been no

headache, no vomiting or vertigo, no edema or shortness of breath. The urine is normal. There is no specific history.

Physical examination made December 20th showed no disease of the radial or temporal arteries, no disturbance of motion, or (objective) sensation. The knee-jerks were normal, perhaps rather active, the plantar reflex, normal flexion of toes in both feet. The general condition was good, the nutrition unimpaired. The fundus was normal; the pupils alike, regular in shape, and reacting both to light and accommodation. The movements of the jaw were extremely feeble in all directions, the lips relaxed, the speech indistinct. The disturbance of the fifth nerve was entirely limited to motion, the lightest touch being felt in the distribution of all three branches. There was external strabismus in the right eye. There was drooping of both lids, more marked on the right. The expression was that of the so-called "Hutchinson face" described in the text-books under ophthalmoplegia. The vision was normal. The diagnosis of poliencephalitis, superior and inferior, was made at this time, and an extremely guarded prognosis was given. The case was classified as subacute and it was uncertain whether improvement would appear, as is common in cases of acute poliencephalitis, or whether steady progression would ensue. The treatment by strychnia, which had been commenced by Dr. Aldrich, was continued, in doses of one-thirtieth of a grain.

When seen at the hospital January 6, 1900, Dr. Aldrich reported that he had been better and worse during the two weeks, but had on the whole steadily improved. It was found that he could now whistle, though with some difficulty, and that the finger inserted in the corner of the mouth was grasped with considerable force by the orbicularis oris. The patient could shut the teeth, and move the tongue in all directions and protrude it, movements which were formerly impaired. (There was no wasting or fibrillary twitching of the tongue.) The strabismus was less marked, the eye following the fingers fairly in every direction, though double vision was still present when looking straight ahead or to the left. The ptosis was practically unchanged. The articulation was somewhat blurring, but he could pronounce the labials, and the linguopalatals, anterior and posterior, perfectly. The movements of the jaw, though stronger, were still very weak; lateral motion and motion forward and back (pterygoids) were feeble, and the attempt to close the jaw could be effectually opposed by holding the chin down with one finger.

The nuclear origin of the lesion in this case is established partly by the bilateral character of the symptoms and partly by the limitation of symptoms to the motor sphere, for it would be incredible that disease involving cranial nerves at the base should spare the sensory fibres of the fifth nerve while affecting all its motor branches. It would, again, be difficult to imagine a lesion of the third nerve elsewhere than in its nucleus, selecting the fibres to the lid and internal rectus, whereas the nuclear groups furnishing these fibres lie in contiguity posterior to the groups for the sphincter iridi and ciliary muscles, and anterior to those supplying the superior and inferior recti, all of which muscles were spared. Furthermore, the involvement of the orbicularis oris at a period when the muscles supplied by the seventh nerve were spared points to involvement of the twelfth nucleus, which probably supplies the orbicularis oris, though the fibres proceed by the way of the seventh nerve.

Cases showing combinations of superior and inferior poliencephalitis are on record but are rare; Dr. Taylor showed one such case from this clinic at a recent meeting of the Clinical Club, the report of which will appear in the JOURNAL. A few cases have been described as "ascending inferior poliencephalitis," in which the lesion gradually spreads from the inferior to the superior nuclei. In this case the first nucleus affected was apparently the fifth; the ninth, twelfth, and probably to a slight extent the seventh, were invaded at about the same time. The affected nuclear groups of the third succumbed within about a month. The case might perhaps then fairly be classed under the ascending form.

The etiology and prognosis of the case are still indeterminate. The patient's own suggestion that excessive chewing was the exciting cause cannot be quite disregarded, especially in view of the initial involvement of the fifth nucleus; it would seem, however, that in this event the onset should have been more insidious. The sudden appearance of the separate symptoms was suggestive of infection, now recognized as the cause in the acute forms of both poliomyelitis and poliencephalitis. Here, however, we are met by the comparatively gradual extension from nucleus to nucleus — in other words, this case came on rather rapidly for the chronic progressive form either of ophthalmoplegia or of bulbar paralysis, and rather slowly for the acute infectious process.

The further progress of the case will be communicated in another number.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

A. K. STONE, M.D., SECRETARY.

REGULAR meeting, Monday, November 20, 1899, DR. R. H. FITZ in the chair.

DR. BEACH reported orally a case of

INTESTINAL OBSTRUCTION

that entered the hospital Saturday afternoon. It exemplifies the importance of the early recognition of obstruction and the necessity for prompt intervention. The patient, a woman, was seized a week before with severe general abdominal pain that never became localized. Shortly after, vomiting began and continued during the whole week until she entered the hospital. It had become fecal after three days. There was moderate distention, but the transverse coils of intestine could be easily recognized through the abdominal walls, which were rather thin. Her general condition was very poor, and operation only offered a possible relief from vomiting, the severest pain having ceased on Wednesday. On opening the peritoneal cavity chocolate-colored coils of intestine corresponding with the external appearances could be seen, distended with fluid and gas. On attempting to turn them out through the incision I found them so unwieldy from their fluid and gaseous contents, that a rupture might easily occur, so I drew a coil over to the side of the operating table, made an incision into

the ileum and discharged from it three quarts of feces. The vicinity of the wound was carefully cleansed with peroxide of hydrogen and the incision closed with a double layer of Lembert stitches. Then that intestine was returned to the abdomen, and by putting the patient into the Trendelenburg position the small intestine gravitated toward the diaphragm. There was to be seen then a tumor, entirely filling the pelvis, which proved to be a cyst of the broad ligament. It was tapped, discharged and the unadherent cyst wall removed. Then, supposing that I had found the whole cause of the obstruction, I tried to push along some of the fluid in the small intestine toward the cecum. I found it impossible, owing to a firm adhesion of a tangled mass of intestinal loops to the left side of the abdominal wall near the ilium. Those were carefully dissected out, the adhesions found to be strong and suggesting that the original lesion may have been an old inflamed tube of the right side with adhesive peritonitis that had extended to the left side, involving the intestine and fastening it firmly to the bone. After the small intestine had been released the fluid contents remaining in the intestine could be easily pushed along to the cecum. The large intestine from the cecum to the rectum contained scybalous masses.

The patient passed through the operation, which lasted one and a half hours, surprisingly well, and was relieved of her vomiting. The expected fatal result occurred on the following morning.

Dr. R. C. Cabot read a paper entitled

SOME POINTS SUGGESTED BY THE CLINICAL STUDY OF 186 CASES OF VALVULAR HEART DISEASE.[1]

Dr. F. C. Shattuck: With regard to the seat of maximum intensity of the murmur of aortic regurgitation, I am a little surprised that Dr. Cabot finds the statements in the books as he does. I know that in many of the books it speaks as if the maximum intensity were usually at or about the aortic area, but I thought — I am speaking from memory — that a good many of the books said very frequently the seat of maximum intensity was about the fourth left costal cartilage. My experience coincides with that of Dr. Cabot that the seat of maximum intensity is to the left of the sternum and about the fourth costal cartilage in the decided majority of cases. I am reminded by this point which Dr. Cabot makes of the time when the late Dr. Calvin Ellis invited me to teach auscultation in the medical school. I told him I should be only too delighted to do so, and he said, "Are you going to teach that the seat of maximum intensity of the murmur of aortic regurgitation is the fourth left costal cartilage?" I said, "Doctor, I have generally found it to be such." Subsequent observation is confirmatory of my earlier experience.

Dr. Cabot speaks very fairly of aortic stenosis, as it seems to me. The signs of pure aortic stenosis are clearly laid down in the books, as theoretically they ought to be. Practically, however, I believe pure stenosis at the aortic valve, without regurgitation, to be a very rare thing. Personally I am not inclined to think that the presence of a palpable systolic thrill in the aortic area is characteristic of stenosis as against mere roughening.

I am rather surprised at Dr. Cabot's statement that he found — I think it was four or five — well-marked cases of aortic regurgitation, sufficiently marked to produce the Corrigan pulse and the pistol-shot sound in the peripheral arteries, without being able to make out any enlargement of the left ventricle. That certainly has not been my experience. Of course the intensity of a murmur, as we well know, is no index whatever of the gravity of the lesion. The biggest murmurs sometimes go with the smallest lesions, and the disappearance of a murmur may be a thing of very serious import, as showing that the heart is not contracting strongly enough to produce the vibration necessary to result in murmur. Of course a very small aortic regurgitation might make a loud murmur, but I should not think it would be likely to produce a well-marked Corrigan pulse and a pistol-shot sound in the crural, for instance. If I got that group of symptoms I should certainly expect to find well-marked signs of enlargement of the left ventricle.

Dr. Morse: I have very little to add, as I agree entirely with everything Dr. Cabot has said. As to the location of the murmur of aortic insufficiency, I have found it most commonly at the left of the sternum and sometimes under the xiphoid. I think it ought to be borne in mind that sometimes the murmur is heard in that location when not in the aortic area at all.

As to the diagnosis of aortic stenosis, I have always felt great hesitancy in making that diagnosis. It seems to me one of the strongest points in favor of it is the character of the pulse, that is, the infrequent pulse with the slow rise. When from the sounds there is apparently a combination of aortic stenosis and insufficiency, the character of the pulse is very important in diagnosis. If the pulse shows the character of aortic insufficiency there can be no great amount of stenosis, no matter how loud the systolic murmur or how transmitted. If, on the contrary, the pulse is not characteristic of aortic insufficiency, the mitral valve being intact, there is almost certainly stenosis also. I have also felt great hesitancy in making the diagnosis of mitral stenosis in the presence of a presystolic murmur. I think we may sometimes be led astray by considering a murmur presystolic which really is at the beginning of systole, and that thus we may be wrong in placing the time of the murmur.

Dr. Folsom: In regard to epigastric pulsation, I think I have seen cases enough to justify me in saying it does not *necessarily* mean anything. I have a case in mind which I saw twenty-nine years ago. The pulsation was so prominent that one gentleman felt sure it indicated an aneurism. Another, a professor of clinical medicine, was quite sure there was something, he could not explain exactly what, and he thought there had been a pericarditis, with adhesions to the diaphragm, and gave a prognosis of consequent progressive enlargement of the heart. The pulsation continued quite prominent for eight or ten years and it finally pretty much disappeared. There is a slight mitral insufficiency and no material enlargement of the heart at the present time. I have seen several cases where I am quite satisfied that very strong epigastric pulsation, giving rise to great anxiety perhaps, does not *necessarily* mean anything.

With regard to mitral stenosis, my great difficulty has been to find any murmur at all, and I think that has given me more difficulty than other condition with regard to that particular valve. I had supposed that the seat of the maximum intensity of the aortic re-

[1] See page 106 of the Journal.

gurgitant lesion was where Dr. Cabot stated it to be, and I had been so long in the habit of considering it so that I had quite forgotten the teaching at the time I was in the medical school, and quite forgotten the fact it was at all generally considered otherwise. I think it has been — I would not say universally so in the cases I have seen, but certainly in a very large majority.

DR. SHATTUCK: Is it possible that this epigastric pulsation may be explained in some cases by a curvature of the spine in that region, a lordosis throwing the heart and great vessels a little farther forward than usual? That would seem to account for some cases of suspected abdominal aneurism.

DR. HEWES: I should like to ask Dr. Cabot if he thinks there is any circumscribed area for the normal apex beat. I ask this in connection with his statement that he found several cases of aortic regurgitation where he perceived no enlargement of the heart, as I understood. I think he said where there was no evidence of enlargement of the left ventricle. In my clinic this year and in former years, I have taken all the normal cases — cases in which the heart was normal — I could find, and tried to locate the apex, and I have found great variation in what we would call the normal position, sometimes as much as three-fourths of an inch in different people, so that it would be quite possible, it seems to me, to have some enlargement of the heart which would make it a large heart for the person in question and yet not be outside of the stated limits for all people. The existence of this variation may account for the apparent lack of hypertrophy in the four cases of aortic regurgitation mentioned. It is difficult to understand how this lesion of the aortic valve can exist for any time without causing enlargement.

DR. SHATTUCK: In a pure mitral stenosis we should have no enlargement of the left ventricle. I have seen this summer a number of cases where I had every reason to suppose I had pure mitral stenosis and yet had enlargement. My general position is that there is no statement any one can make about the connection between any form of cardiac disease and any kind of hypertrophy, and I think I have cases which will justify that. No one can say any form of cardiac disease is always accompanied by hypertrophy of one or the other ventricle, or that in such hypertrophy is always absent in it. I think we have to take a perfectly general and "expectant" position in regard to these points.

DR. CABOT: I am very much in a questioning attitude. Dr. Folsom says that the epigastric pulsation may not mean anything. I should like to ask what it does mean if it does not mean cardiac disease.

Then I want to have another question answered, as to what we are to do in these cases of presystolic murmur clearly recognized at the apex in the presence of an aortic regurgitation; are we to suppose the smallest number of causes possible and say there is no mitral lesion, or say that we do not know, or what is the proper and scientific thing to do? What are we to say to our patients? What are we to write in our diagnosis books?

In regard to Dr. Hewes's question as to where is the normal apex, I have gone on the general supposition that an apex in the normal position was one in which the percussion dulness (agreeing with the outermost points at which you could feel any rise and fall of the chest) was within the nipple and not lower than the fifth space.

DR. FITZ: When I was accustomed to control clinical observations by autopsies I observed that not infrequently lesions of the heart were found that were not expected and were not found when expected. As regards the question Dr. Cabot has raised with reference to the diagnosis of mitral stenosis, I would say that I lay much more stress upon pulmonic accentuation and hypertrophy of the right ventricle than upon the characteristics of the murmur at the apex.

DR. WALTER E. PAUL read a paper on

EPILEPSY.[2]

DR. WALTON: Dr. Paul has opened a subject too large to discuss exhaustively, even in the three directions from which he has approached it. It is always of interest and value to hear from one who has treated a large number of cases of a disease so well recognized as this one, to know, for example, how far the clinical types and treatment really agree with the text-books. In regard to the etiology, which Dr. Paul has touched upon, although this branch was not included in his subject, there are several points of interest. I thoroughly agree with Dr. Paul's position that although toxins may act as the exciting cause of an attack, the real underlying condition is a defective neural endowment; that is, these patients are degenerates, unable to stand the stresses to which we are all subject. Under etiology I should like to speak of two symptoms which have been mentioned in connection with epilepsy, namely, infantile convulsions and migraine. It is, I think, not infrequently taught that infantile convulsions, even though disappearing, tend to produce or to forerun epilepsy later in life. Again, migraine has been spoken of even in text-books as a sort of equivalent for epilepsy, and the fear has been held out in some instances that migraine may precede a tendency to epilepsy or that one may replace the other. I saw, not long ago, such a reference by a Russian writer. These two suggestions, it seems to me, lead to an unnecessary fear. Dr. Carter and I have studied the subject of infantile convulsions, examining a great many epileptics with regard to this point. We found no greater percentage of epileptics who had had convulsions in infancy, disappearing to return again as epilepsy, than we found in ordinary individuals. We did find, however, quite a number of cases in which the convulsions became continuous and led to epilepsy later in life. We drew the conclusion that given the case of an infant suffering from convulsions, we cannot assure the parents that that child will not become an epileptic, but we can say the chances are against it, because out of many such cases only a few become epileptics. We can, it seems to me, fairly assure them that if a child has ceased to have convulsions and grown to the age of twelve or thirteen, he is no more in danger of epilepsy than another child.

In regard to migraine, exactly why this symptom has been deemed analogous to epilepsy it is rather hard for me to see. In the first place, the absence of consciousness, which is the distinctive feature of epilepsy, is entirely wanting in migraine. In the second place, the sudden onset, the fall, the personal injury, is not even suggested in migraine; there is entire ab-

[2] See page 107 of the Journal.

sence of convulsion or anything of the sort; in fact, the whole picture is one from the sensory side, whereas epilepsy is evidenced largely on the motor side. It has occurred to me recently to start an investigation of epileptics with regard to the number of cases of migraine. I have only had a chance, so far, to question 35 patients, but this number already has brought out one or two interesting features. In the first place, it *has* shown a rather large proportion of migraine. Out of 35 patients, 13 gave a perfectly distinct history of migraine preceded by a blur and nausea, vomiting, malaise and headache lasting from a few hours to a day or over night. This does tend to favor the proposition that these two diseases have a common parentage, that they both occur perhaps among degenerates, still it is a long step from accepting this proposition to deciding that one stigma of degeneration will lead to the other, because, as we well know, almost every one has one or more signs of degeneracy; we are, however, far from deciding on this account that one is likely to become an epileptic. I should say with regard to these 13 cases, that although they may show a common parentage, yet they are far from indicating that migraine led to epilepsy, because in only four had the epilepsy occurred before the migraine, and of the four in which this was the order, all were typical cases of migraine, beginning at the usual time, namely, ten, twelve to fourteen years of age, and of those four cases one had been completely restored by use of proper glasses. All of them, by the way, had errors of refraction which the oculist to whom they were sent decided were quite sufficient to produce migraine, with the exception of one case of myopia, not, I believe, a common cause of migraine.

Coming to the question of complete loss of consciousness in diagnosis, I agree with Dr. Paul. All the text-books say so also, that complete loss of consciousness is the one characteristic feature of epilepsy without which we are hardly justified in making a diagnosis. I have been in the habit in my clinical exercises of having a half dozen or more patients recognized as epileptics brought in, and making a chart upon the board with the number of the case down the left-hand side, dividing the chart into squares and at the top writing the various symptoms of epilepsy, loss of consciousness, onset of attack (sudden or gradual), question of drooling or frothing, biting the tongue, injuring the face, passing the urine or feces, the cry, the aura, etc., and it invariably occurs that the one list which is uniform is the list under the head of loss of consciousness. They all have complete loss of consciousness, although by no means all drool or froth, and only perhaps half have an aura, or perhaps half void the urine. This is an important point in diagnosticating epilepsy from hysteria, while medico-legally it is of the utmost importance in deciding whether a person who has performed a criminal act is to be adjudged a criminal or epileptic. Another important point is in connection with treatment. It is an undesirable thing to put hysterical patients on continuous bromide treatment. I have generally found in the doubtful cases, however, it is wise to regard them and treat them as epileptics.

Coming to medico-legal cases this question of loss of consciousness is a very important one. I remember a lecture of Wagner's in Leipzig, in which I understood him to say that a certificate should never be given of epilepsy unless the physician had seen the patient in an attack. It certainly is true that we should not accept unquestioned the mere history of absolute unconsciousness, when there is an object to be attained by giving the history of epilepsy, as, for example, in the case of a criminal. A history of loss of consciousness may come from one or two other causes: the first is the good (or rather bad) old-fashioned one of lying, which, somehow of late, in medico-legal investigations, seems to be going somewhat out of vogue, but, unfortunately, it has not gone entirely out of practice. In short, when we find there is an object to be attained, we should investigate the case with the greatest care and not rely implicity on the patient's statement. The second cause of mistake in diagnosis in these cases is alcoholism. It is not infrequent in murder trials to find the diagnosis of epilepsy brought up in defence in cases in which a considerable amount of alcohol has been taken. Now in these cases it seems to me that unless the history of epilepsy is very strong, and unless the proof is very clear that this was the occasion of an epileptic attack, if the person has taken a considerable amount of alcohol, the benefit of the doubt should be given to the alcohol and not to the epilepsy.

It has been demonstrated that epileptic attacks produce forgetfulness, not only for what has occurred during the epileptic attack, but for what has occurred immediately preceding the attack — so-called retrograde amnesia. Although this may be possible, it is certainly a rarity, whereas it is a common thing for a person under the influence of alcohol to go on, more or less in an automatic way, perhaps with conversations, and to carry on, I will not say his ordinary duties, but his ordinary pleasures, apparently conscious at the the time of what he is doing, but retaining no memory of his acts.

It has been asked whether an attack of vertigo can be regarded as an attack of epilepsy. There are certainly many equivalents of epilepsy and one equivalent is a temporary giddiness in which the person loses consciousness, but recovers so immediately that he does not fall. This may be called a true epileptic vertigo, but when it comes to deeming vertigo without unconsciousness epilepsy, I should be inclined personally to draw the line. When we remember what a number of causes there are for vertigo, such as disease or disorder of the eyes, ears and stomach, if the person feels a tendency to fall in one direction or another, or really does so, retaining his consciousness, I should not regard that as epilepsy.

On the subject of treatment I have nothing to add except to emphasize the importance of institutions in which epileptics are kept as far as possible at work in the open air. The worst thing for an epileptic is to be continually watched, attended like an invalid, and guarded from all danger. I always tell parents that, far from doing this, they should take their chances within certain limits, remembering that with every child chances have to be taken when he goes bathing, sailing, or riding a bicycle, and that even if such sports were allowed, the chances would be only somewhat increased in case the boy were liable to an occasional attack of epilepsy. Certainly as far as the less dangerous sports are concerned, the advantage to be gained by watching a person every moment is nothing compared to the injury done by making him morbid on account of the feeling that he is continually under observation.

DR. E. M. GREENE: I do not know why I should be asked to speak unless it is desired to hear from a general practitioner who is more interested in the treatment of these cases than in the more refined scientific points. It seems to me that this idea of the epileptic as a degenerate is being more emphasized than it used to be, and that this degeneration shows itself not only in defective physique, but also by an impaired mental condition, or one which is very likely to become impaired in the future. In this connection a history of alcoholism in the parents is said to be much more frequent than the direct heredity of epilepsy. The hopeful thing at present, it seems to me, is the idea of establishing colonies for epileptics and giving them outdoor life, regular exercise, preventing any occasion for excitement, such as might occur in the evening in a city, and which is absent in the institution treatment, and also carefully regulating the diet. Epileptics are usually great eaters and very injudicious, and it is extremely hard to get them to carry out the proper diet that is prescribed for them. Now, looking at the epileptic as a degenerate, there are two ideas which occur to me which have a bearing on the treatment, especially the drug treatment. We see stated in the text-books the importance of using bromide in large doses, continuously, and for years after the attacks have stopped, in order to prevent their returning, and, on the other hand, we see almost nothing in regard to this newer idea of hygienic regulation of the epileptic's life. In these institutions I am told that very little bromide is given and in some cases not a dose. Personally I have seen some bad results from the use of bromide and, although it is in many cases very useful, yet we should not use it in a routine manner. For instance, to give three illustrations of harmful effects, I have seen in the case of a middle-aged man, who was the proprietor of a liquor store and led a very exciting sort of life, and had some chronic interstitial nephritis, that the effect of bromide was extremely depressing. While taking doses of only ten to fifteen grains three times a day, after a number of months he became strongly suicidal and was in a condition of mild melancholia. I let him go without the bromide, and could not see that he was any the worse for omitting it. Taking a vacation and going to Florida for several months, as he did in three successive years, he was very much relieved. When he came back to work he hated the bromide so much that he took quack medicine instead, and it is my experience that a great many of the more confirmed epileptics do resort to quackery, thus giving conclusive proof that the treatment which they have previously had from regular doctors has been unsatisfactory to them. This quack medicine, which did not taste at all as if it contained bromide, apparently accomplished more than the bromide had, although of course we must remember that the disease has its curious turns apart from treatment. In another case of an aged lady, whom Dr. Folsom saw this summer with me, where there was cerebral arteriosclerosis and typical epileptic attacks, bromide was exceedingly depressing. It was given in ten-grain doses only three times to control mental excitement and restlessness. On the first two occasions the patient went into a comatose condition which lasted some eight hours or more and which I attributed at the time to the progress of the disease and looked for a bad result. The patient recovered and went on in a very satisfactory condition for a while. A third trial of bromide caused exactly the same state of affairs and I then concluded that it was more dangerous to give ten grains of bromide to this patient than one-fourth to one-half grain of morphine to an ordinary individual. Then in a third case I have seen bromide pushed to such an extent as to produce delusions and hallucinations of sight and of hearing in a person who had never shown any symptoms of insanity. The patient was sent to the McLean Hospital while I was resident there and treated without any medicine, simply as an insane person, and in about a week the symptoms began to disappear; the patient became entirely rational. It seemed to me in the anxiety to control the attacks in this case the doctor might have pushed the treatment in a routine way altogether too far. I have a feeling that, if, after a thorough trial for several months, the general condition of the patient is not satisfactory nor the number of attacks diminished, I should be very much inclined to give extremely small doses or omit it altogether, and preferably to substitute the outdoor life of a colony.

Another point which seems to me important, and which is emphasized in the text-books without very much evidence in support of it, is in regard to the question of omitting meat from the diet. If these people are degenerates, in a poor physical state, we do not want to depress their vitality by large doses of bromide, while at the same time interfering with their nutrition by depriving them of the valuable proteid elements. Some of the text-books advise entire abstinence from meat; almost all of them cut it down to a small amount once a day. I notice in the text-book of Wood and Fitz that the allowance of a moderate amount of meat twice a day is considered beneficial and the contrary treatment, entire abstinence, is regarded as of no value. In regard to this particular point, I have in mind a patient who was a poor man and went to the Massachusetts Hospital, where he was told to abstain entirely from meat and given a good deal of bromide, which was practically carrying out the treatment I had already given him. The attacks did not diminish at all and the man, getting discouraged, did as he pleased. I do not think he had carried out directions in regard to diet strictly, but when he gave up the attempt and indulged in meat as much as he liked and neglected to take bromide, he went two years without having any attacks at all. I should like to have some good evidence in regard to this diet question. In private practice this is very hard to get, but in these institutions the question ought very soon to be settled exactly what sort of diet is satisfactory, because there the diet can be absolutely controlled.

DR. FOLSOM: The diagnosis of epilepsy, of course, in the enormous majority of cases is very simple and the number of cases where there is any difficulty in diagnosis comparatively small, so that does not interest the physician in general practice very much. I do not know that I understand the reader and Dr. Walton, but if I do, it seems to me there are a good many attacks of epilepsy which they are inclined to deny, that is, cases of people who perform acts which seem to be entirely intelligent to persons observing them, and yet where there is complete amnesia. With regard to the etiology, the cases that I see now are usually people in fairly good circumstances in life, and very few of them are degenerates; a very decided minority are degenerates, and in looking over my

cases some time ago, I was surprised to find the large number of people in absolutely perfect physical condition, so far as one can see, and where the condition seemed to be due to a severe injury to the head or to successive injuries to the head. In regard to prognosis, it seems to me there are very few cases where one cannot do a good deal in epilepsy provided there are no signs of degeneration and no indications of decided mental trouble. I think after an epileptic begins to be distinctly demented, it is rather unusual for medical treatment to be of much avail, but I think before that if they show signs of dementia or organic trouble, in the vast number of cases the number of attacks can be enormously reduced in frequency and in severity. I do not think that that means always the giving of medicine. I think quite a number of cases do better without medicine of any kind than they do with any of the drugs which have yet been recommended for epilepsy, but the one which everybody finds of the greatest use, of course, is bromide in its various forms. Personally, I rarely give bromide of potassium or sodium, because they are more depressing to the heart than the ammonium or strontium and the bromide of sodium is more disagreeable in taste, but I think in the vast majority of cases a great deal can be got by giving them. There are various ways. One way is to begin with enormous doses and get the patient thoroughly bromidized. In my experience that does not do well at all. If you have your patient under your care for a few months you are more apt to get a striking diminution in the attacks, a more brilliant temporary result, but the ultimate result is usually bad. The vast majority of cases have to be treated many years. The way I have found most successful is to watch them closely and give the maximum amount of bromide which they can take without injurious effect. Of course some people get bromidized after small doses, some cannot take bromides at all in any form or quantity any more than iodides, and I rarely give either of these drugs in any considerable dose without their being under my observation almost daily for a sufficient length of time to be sure there is no idiosyncrasy and that you get no toxic action of the drug. Of course the cessation of attacks for a long time does not necessarily mean cure. I do not think I have ever seen in my life a case of epilepsy in which I felt satisfied of absolute cure. I have seen them go five, ten, or even twenty years without attacks, and have seen quite a number of cases I thought were cured, but in ten to fifteen years the attacks would come back, and one could hardly call it a new disease. I remember one gentleman who had attacks up to the time he was twenty years old, and they ceased forty-five years, until he was sixty-five. That is, of course, rather unusual. I do think you can get very satisfactory results in the treatment in the vast majority of cases. I think diet makes a great deal of difference. I don't think it makes much difference in the cases you would get in a colony provided you give a reasonably sensible diet, but patients whose nervous systems react rather readily I think are helped a good deal by a very careful diet. With regard to the manner of life, if people are reasonably intelligent, I let them regulate their lives themselves. I think it is the best way to do. They know what is likely to occur and they can regulate their lives accordingly. I remember a gentleman who was under my care some years whose life I did not think it was worth while to regulate much in that way, and who saw two of the leading consultants in London at my request, and they advised him never to go anywhere unattended, never to be alone under any conditions whatever. He came back to this country and said that a few weeks of that satisfied him, that he would be nothing but a vegetating being in a short time, and led his life; went to riding horseback and canoeing, and in one of his attacks his canoe capsized and he was drowned, and I have no doubt he would say he did the best thing. A young lady, now a patient in this community, rides horseback, jumps over a three-foot fence on that same theory, and I am inclined to think on the whole she is sensible. She says that the minute she begins to restrict her life, her life is all gone, her usefulness ended, so that it seems to me that is a matter one has to leave very largely to the patients.

Dr. Knapp: I have been rather interested in the last few years in the discussions which have taken place as to the toxic theory of epilepsy, especially in the French journals, by an opportunity I have had of comparing the application of the theory to two patients who have been under my care for several years. In one case the patient tried his best to follow a careful régime, yet almost every attack that he has had for a period of half a dozen years could be traced directly to some disturbance of his digestion, or indiscretion in his diet. The other man, when the question of regulation of diet was brought up, said: "I will try to do what I can, but you know a man going out and dining must eat and drink what is set before him, and I cannot always follow a restricted diet." He has had fewer attacks than the other patient, and in no instance, with a single exception, in five or six years, have I been able to trace any connection whatever between any digestive disturbance or indiscretion in diet and the occurrence of the fit. Two cases, of course, in themselves, are of little importance, but it has always seemed to me that the toxic theory is by no means sufficient to explain the epilepsy excepting, as Dr. Paul and Dr. Walton have said, as an exciting cause of the individual attack.

In regard to the diagnosis, I agree fully with Dr. Walton in questioning very much the relation between migraine and epilepsy. We have all of us seen patients who have had migraine for very many years, whose children after them have had migraine, and yet there has been no history whatsoever of epilepsy in the family. I have not gone over my statistics of cases of epilepsy carefully, but my own experience is that very few cases of epilepsy have complained of anything like a typical migraine attack.

I am not quite so ready as Dr. Walton is to regard convulsions in infancy as a mild affair. I think if a child has convulsions it is an indication that the child's brain is a more unstable brain than that of the ordinary child. I admit of course that a young child will have convulsions from an exciting cause which the adult brain will not have, and when a child is brought to me with the history of convulsions in infancy I do not prognosticate epilepsy by any means, but I think that such a child is one most certainly to be watched. A considerable number of those cases in my experience have developed epilepsy later. In other cases the convulsions have proved to be the beginning of some structural disease in the brain, such as hemiplegia or some defective development of the brain leading to imbecility. I unfortunately did not hear the beginning of

Dr. Paul's paper, so that I do not know whether he brought up the point of the necessity for careful examination to see whether there is any trace of infantile hemiplegia which may be the cause of the epileptic trouble. I have found traces of infantile hemiplegia in a certain number of cases, although I think not quite so frequently as Dr. Sachs, of New York, has claimed. Convulsions in infancy, however, are somewhat serious, and I think that such a child should be carefully watched lest in later life trouble develop.

On the question of loss of consciousness I should agree in the main with what has been said. I think that loss of consciousness is the essential factor in making the diagnosis, yet I recall certain cases of undoubted epilepsy where occasionally in the attacks of petit mal the consciousness was not wholly lost. The patients have said that they retained a certain consciousness of what was going on about them; they sometimes have been able to give a correct account of things which were said or more rarely of things which were done during the clouding of consciousness of the petit mal. Furthermore, I have had occasion to question more than once whether the loss of consciousness could be regarded as a definitely distinctive symptom in the diagnosis between epilepsy and hysteria. I have had under my care this summer one of the most trying cases of convulsive attacks that I have ever had anything to do with in which the patient was certainly hysterical to the most extreme degree, presenting the typical stigmata of hysteria. He had attacks which were undoubtedly hysterical attacks, yet he had others in which there was a simple loss of consciousness without convulsion, and it was very difficult to determine whether those could be regarded as epileptic or as hysterical. And in the attacks which seemed more definitely hysterical he went through various automatic purposive movements, yet there was a complete loss of memory for what took place. One feature which had certain weight with me in deciding that there was a mixture of the two diseases was the fact that not infrequently the convulsive attack whose nature was doubtful came on during sleep; he was attacked in his sleep and thrown out of bed in the violence of the attack.

In the ordinary routine treatment of epilepsy I do not go quite so far as they do at the Massachusetts Hospital in the absolute cutting off of meat. I usually allow meat or fish once a day, but as a rule I advise against taking it at night, taking it either in the morning or at noon. My experience with patients is that the great majority of them are fairly ready to follow such regulations. One writer on epilepsy — I think it is Gowers, but I am not quite sure — has questioned whether meat really were so injurious to the epileptic as a good many of the text-books say, and I confess that I am still somewhat in doubt. I think we cannot lay down any absolute rule. We must treat the individual case, and we must especially study the patient's nutrition carefully; if we find under the limitation of meat that the patient is getting weak and pulled down, it becomes necessary to build him up in whatever way we can. In the routine treatment, furthermore, I depend chiefly upon the bromides. Dr. Greene has just spoken of the bad effects of bromide, and of the fact that the text-books say so little about the necessity of cutting off bromide. Dr. Peterson recently has argued quite strongly in favor of the complete cessation of the bromide in chronic epileptics who had been taking it for a long time. I think that in any event when we are giving bromide we must watch the patient carefully and be guided, not by any general rules as to whether it is desirable to cut off bromide or not, but by the patient's condition. Personally I have seen the bad effects of the large doses of bromide, getting the patient into a condition of bromidism, often enough so that I want to watch the cases very carefully and keep them, as Dr. Folsom has suggested, with about as much bromide as they can comfortably tolerate without getting them into the condition of bromidism.

The Flechsig treatment I have not had the opportunity of carrying out in its detail. I confess that to give the patient the doses of opium which Flechsig has recommended seems to me a somewhat risky thing in the ordinary patient who is wandering about and whom you cannot keep under your control; therefore, in the out-patient clinic I do not like to give it and unless I can absolutely depend upon the patient in private practice to report at the appointed time I hesitate then.

There is one modification of the bromide treatment which Dr. Paul did not speak of which has seemed to me a very valuable one in a considerable number of cases, and that is the combination of the bromides with some cardiac tonic, especially the mixture of adonis vernalis with codeia as recommended by Bechterew. I would agree fully with what Dr. Walton and Dr. Folsom have said about the bad effect upon the epileptic of putting him into too confined a life and forbidding him to do the things which he wants to do and desires to do. In that way I have been somewhat skeptical, I must confess, in regard to the advantages of the colonies for epileptics. Of course there are many cases which must necessarily go to a colony, but at the time the epileptic hospital at Monson was started I went over rather carefully a good many of the cases of epilepsy that had been under my care, and it seemed to me that on the whole, as they had gone on, it was not altogether the best thing to send them to an institution, to put them into a routine life where they were cut off from a good many of the enjoyments of their lives, and where they could not lead the ordinary life of the community which they were leading fairly well and which did not seem to harm them. In the same way we can recognize the possibility of harm to an epileptic from riding the bicycle, sailing, etc., but it is a risk which I think it is, on the whole, better for the ordinary epileptic to take who is having a convulsive attack once in two, four, six weeks or six months, than to feel that he is living an invalided, restrained, cramped life.

DR. PAUL: I would like to correct Dr. Folsom's impression that Dr. Walton and myself do not recognize the psychical equivalent of epilepsy.

Recent Literature.

Nervous and Mental Diseases. By ARCHIBALD CHURCH, M.D., and FREDERICK PETERSON, M.D. Pp. 843, with 305 illustrations. Philadelphia: W. B. Saunders. 1899.

Although bound in one volume this is really two separate treatises, one of which has since appeared in-

dependently. Of these Dr. Church has written the treatise on nervous diseases and Dr. Peterson the treatise on mental diseases. The principle of division is the old one — affections usually requiring restraint are called mental diseases, those rarely requiring restraint nervous diseases. The authors have missed an opportunity to write a treatise on diseases of the nervous system which should deal with those diseases as a whole, emphasize the need of psychiatric examination in all diseases of the brain, and describe paranoia, general paralysis and other cerebral affections which are apt to require restraint in their treatment, in their proper relation to other affections of the brain. By adhering to the old division there is considerable repetition in the introductory chapters of the two sections. The first part of the volume, on nervous diseases, is a fairly good presentation of the subject, although not fully abreast of our present knowledge. No notice is taken, for example, of Flechsig's association centres in the chapter on cerebral localization or of Dejerine's views in the chapter on aphasia. The style, moreover, is often obscure and involved, and the clearness so essential for the beginner is lacking. The work is, however, fairly complete in its presentation of the diseases of the nervous system, the conclusions are usually sound, and the illustrations are many of them original and good. The second part of the work, on mental diseases, is more clearly written, but its classification and description of mental diseases is much more antiquated. Great and unwarranted emphasis is placed on the stigmata of degeneracy, to which one-tenth of the second part is dedicated. Heredity is made prominent, without a word as to modern ideas questioning the possibility of inheritance of acquired characteristics. Strain is put forward as the other important causative factor, in which, as we find later, toxic influences are included, but the influence of toxic causes is not sufficiently emphasized. The classification, always a stumbling-block and always unsatisfactory, is old fashioned. Mania is the first affection described, and we hear nothing of the doubts as to the existence of mania as an independent disease. We read much of the exaggerated flow of ideas, and little as to the possibility that all mania is but a manifestation of periodic insanity. We find no mention of confusional states, and scanty mention — a trifle over a page — of primary dementia, while eighteen pages are given to the autobiography of a paranoiac, something over twice as much as is given to the account of the disease itself. Failing a work which should present the so-called mental diseases in their true relation to other diseases of the brain, it would have been desirable to give a more modern presentation of the subject for the student. Good modern books on insanity in English are rare. The discussion of insanity in the present work, however, is hardly to be commended.

Surgical Anatomy. A Treatise on Human Anatomy in its Application to the Practice of Medicine and Surgery. By John B. Deaver, M.D., Surgeon-in-Chief to the German Hospital, Philadelphia. In three volumes. Illustrated by about 400 plates, nearly all drawn for this work from original dissections. Vol. I. Upper Extremity; Back of Neck; Shoulder; Trunk; Cranium; Scalp; Face. Philadelphia: P. Blakiston's Son & Co. 1899.

The first volume of this notable work is an extremely handsome book of six hundred pages, illustrated by one hundred full-page plates, most of them from original dissections. In this respect the book is a noteworthy exception to the majority of anatomical and surgical text-books, which are too apt to be content with plates borrowed from other and older works. The artistic work is excellent and details of structure are so well brought out that the plates resemble good dissections far more closely than those in the majority of other works of this kind. Superficial surgical anatomy and the lines of incision and dissection for operating on the nerves and arteries are admirably illustrated.

The descriptive text is in the main concise and clearly written. The book is eminently practical, and replete throughout with references to the surgical application of anatomical points, a feature which adds greatly to its value, by giving a practical interest to a large number of anatomical facts which the student is apt to regard as dry and uninteresting.

From the practical surgeon's point of view the surgical part of the work is not sufficiently full to enable it to take the place of works on operative surgery.

The excellence of the plates and text, however, will render it of great value to the surgeon in looking up the anatomy of special regions to be operated upon, so that it will prove a valuable addition to his working library. When the work is completed by the issue of the remaining volumes, the author and publisher will have the credit of having issued one of the handsomest as well as most complete and comprehensive works on the subject in existence.

The Hygiene of the Mouth. By R. Denison Pedley, F.R.C.S. (Edin), L.D.S. (Eng.), Dental Surgeon to the Evelina Hospital for Children, London. London: J. P. Segg & Co. Philadelphia: S. S. White Dental Mfg. Co.

This is one of the most important volumes on the subject of hygiene that we have seen. Its usefulness will be only limited by the extent of its circulation. The author has gathered a startling array of statistics from schools and hospitals, showing how widespread is dental caries in both the temporary and permanent teeth. He points out with great directness the evil results of decayed teeth upon the health of the sufferer, and cites many very interesting cases which show how far reaching in its disastrous consequences an unhygienic condition of the mouth may be.

The author has treated his subject with an earnestness and simplicity that is most convincing. He has refrained from advancing new theories for prevention or new methods for treatment, but he has sounded the alarm in no uncertain voice and pleads that the evil may be honestly faced and so far as possible eradicated. The book not only deserves to be in the hands of every physician and dentist, but should claim the attention of intelligent laymen as well.

Sanitary Progress in Guam. — In a recent report by Captain Leary, Governor of Guam, it is stated, according to the *Medical Record*, that all precautions are being taken to improve the sanitary condition of the station but a suitable water-supply system is necessary in order that the ground cisterns and wells may be closed and sealed, as they are now contaminated. The evaporating plant at the station is nearing completion, and the sewage system from the government houses to the ocean will be finished in a short time.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, FEBRUARY 1, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

REPORT OF THE SURGEON-GENERAL OF THE ARMY.

As was to be expected from the expansion of our possessions, this last report of the Surgeon-General contains much matter which has not hitherto appeared. The exigencies of the war, of necessity, brought about many changes in the personnel of the Medical Department of the Army, much of which is already familiar to our readers. These matters relating to the hospital corps and nursing are discussed in detail, and the old story of Chickamauga and other camps again officially narrated. The facts of overcrowding and bad management generally are stated in an unvarnished fashion, and the reader is left in great measure to draw his own conclusions.

A statistical résumé of medical matters in Cuba, Puerto Rico and the Philippines is of interest, as showing how large a responsibility is being thrust upon the army medical service, and, we may also say, how well it is being met. This portion of the report is embellished by a number of half-tone photographs of hospitals in those countries. The hospital ship also comes in for its share of attention and illustration.

The *Bay State* receives rather scant notice and does not appear to have impressed the Surgeon-General with her usefulness. No mention is made of her service in transporting the sick during the war to northern ports, and in general the statements regarding her are less flattering than one could have wished. We quote the report's words in full:

"The hospital ship *Aid* was purchased from the Massachusetts Volunteer Aid Association in November, 1898. This vessel, formerly a fruit steamer, had been fitted up at considerable expense by the people of Massachusetts, and under the name of the *Bay State* was reported to have done good work during the previous summer. It was found, however, after a short experience during the occasionally severe weather of the winter months, that her motion in a seaway was such as to render her unsuitable for the transportation of sick. While in New York Harbor getting ready for sea her ice machine exploded, killing one man, injuring 11 others, and causing much damage to her machinery. Her first voyage was with medical supplies to Santiago, Cuba, which she reached December 24, 1898. Thence she proceeded to Kingston, Jamaica, and Havana, Cuba, returning to Savannah, Ga., for more supplies January 24, 1899. She was then ordered to Cienfuegos, Cuba, the intention being to use her as a supply ship and floating hospital for posts on the southern coast of the island, but early in March, having suffered considerable damage from storms, her commanding officer, Capt. A. N. Stark, assistant surgeon, United States Army, was directed to take her to Newport News, Va., for repairs. Here she was turned over to the Quartermaster's Department, and her hospital property and personnel were carried by the *Missouri* to Havana, Cuba, to be used in outfitting the transport *Terry* as an extemporized hospital ship."

The statistics concerning the various diseases occurring in the army call for no detailed mention. The effects of typhoid fever were something appalling during 1898; 4,130 cases occurred in the regular army in that year, divided as follows: In the first quarter, 16 cases; in the second, 131; in the third, 3,089; in the fourth, 894. The usual bane of armies, venereal disease, shows 3,727 cases, fewer by several hundred than the cases of typhoid fever. Altogether, in spite of the good work now being done, the report is not altogether pleasant reading, in view of all that was left undone during the period it covers.

MILITARY SURGERY IN SOUTH AFRICA.

THE stubborn resistance with which the Boers are meeting the British in South Africa has opened the eyes of the world to the thoroughness and adequacy of their preparations for the war, and led to no little criticism of the British Government and the War Office for alleged lack of preparation, and underestimation of the character and amount of resistance which was to be expected. Transportation and distribution of men and supplies seem to have been most effectively provided for. Whatever shortcomings, such as lack of cavalry and artillery, inadequate scouting or whatnot, have been brought to light with regard to the various branches of the service, one branch, the Royal Army Medical Corps, may be said not only to have shown no inefficiency, but on the other hand to have proved more than equal to the arduous tasks imposed upon it, both in preparation and execution. Sir William MacCormac, writing to the *Lancet*, after an inspection of the army hospitals at the Cape and in Natal, and having been present himself at the battle of Colenso, both at the field and base hospitals, as consultant and operator, writes to the *Lancet* that "in all the details of the necessary movements of the sick and

wounded, no army has ever been so well provided as ours is now in the field." He speaks in the highest terms of the medical arrangements as leaving nothing to be desired and expresses surprise at the wonderful recoveries and the very small death-rate. Universal testimony is given by those who have been at the front, that the surgical results are exceptionally good. This is no doubt partly attributable to the favorable nature of the Mauser bullet wounds, and to the healthful climate of South Africa, but the use of antiseptic dressings, the care taken to secure surgical cleanliness, the coolness and skill of the surgeons in the field, and the excellent arrangements for prompt aid and transportation of the wounded must be given no small share of the credit.

At the battle of Colenso a hospital train was actually run into the scene of action, and was ordered back by the chief medical officer when two shells burst close to it. The wounded were taken to the train directly from the field and all the wounds had been dressed, and dressed extremely well, under fire. "Very few of the dressings needed readjustment, and rifle-splints and tourniquets had been adjusted carefully and deliberately, under circumstances of great difficulty and danger."

At the field hospitals at Chieveley, which were situated on a hill about 400 yards outside the fire zone during the battle, there were three operating tents, where some 800 patients were treated during the day (December 15th). "The way in which the wounded had been dressed upon the field, and each man ticketed with the nature of his wound, his name and regiment, was excellent, and extremely useful for purposes of identification." The more trivial cases were sent to the tents, the severer cases redressed and operated upon by the four surgeons of the field hospitals and the three surgeons of the bearer companies.

Ambulance after ambulance, and stretcher squads in continual succession, poured in their quota to the long line of wounded, who lay in rows outside the hospital tents awaiting their turn. The work performed in the operating tents was of great efficiency, the operations being deliberately carried out with skill and despatch under the very trying circumstances of intense heat, hurry and excitement all round. The surgeons on duty began work at 3 A. M., and when Sir William visited them in the evening, they were still at it and continued for hours afterward without food or rest. As soon as the men were treated at the field hospitals, the hospital trains took them rapidly away to the base. Five trains carrying on the average 100 wounded each left between 2 P. M. on the 15th and 8 A. M. on the 17th. This wonderfully rapid and efficient work at the field hospitals was only made possible by the still more remarkable and heroic services of the medical force on the field and the 2,700 ambulance bearers under Major Stuart Wortley, who was able to report at 5.30 P. M. on the 15th, that the whole field had been cleared of wounded. During the battle Captain Hughes, R. A. M. C., on General Buller's staff, was killed by a bullet which severed the innominate artery, and Major Brannigan, R. A. M. C., was shot through the foot.

The hurried notes taken by Sir William at the field and base hospitals, though necessarily incomplete, teem with instances of remarkable recovery from Mauser bullet wounds of the head, the chest and the abdomen. Bullets traversing a lung, and sometimes both lungs, frequently produced no more symptoms than a slight hemoptysis, and almost invariably did well. One man who ran five hundred yards after a bullet had traversed his right lung, entering near the sternum and emerging near the spine, had no other symptoms than a slight hemoptysis, and was doing well when the notes were taken. Abdominal wounds where the positions of the openings of entrance were such as to make it seem impossible that the bullet had not perforated the intestines or stomach made excellent recoveries without symptoms.

The wounds which Sir William saw but a few hours after they were inflicted showed small openings of entrance and exit. Hemorrhage was exceptional, and the subsequent course of the cases was almost invariably aseptic, healing taking place rapidly under a scab. With regard to the remarkable recoveries after abdominal wounds, the conclusion becomes almost inevitable that the small punctures close up without leakage or extravasation. In these cases, as Sir William writes, "either mortal damage is inflicted, when no operation is possible, or the injury is recovered from without inconvenience to the sufferer."

A similar experience with the results of abdominal wounds by the Mauser bullet fell to the lot of the surgeons of the United States Army during the fighting before Santiago. Of head injuries Sir William writes: "The most extraordinary head wounds with damage to the brain seem in many instances to entail no mortal results."

The medical history of the Transvaal War bids fair to add immensely to our knowledge of military surgery, and the prognosis and treatment of wounds by the long-range, small-bore rifle with jacketed bullet. But however great may be the scientific results of this deplorable conflict, the medical profession throughout the world have already reason for pride in the heroism and efficiency of the medical officers on the field. May the work of the Royal Army Medical Corps deal a finishing blow to the fiction that the medical officer, as far as personal exposure is concerned, is a non-combatant! The following note is quoted by the *British Medical Journal* from the *Morning Post* of January 12th, written by the war correspondent of the latter at Magersfontein: "It is most necessary here to say a word in praise of the Royal Army Medical Corps, who faced a hot fire all day long, going close up to the firing line to bring back our wounded. It seems almost incredible that during the day five hundred wounded men should have been brought back by the Medical Corps, though to get them back stretcher bearers and searchers had

to cross and recross a zone of fire at least a mile wide."

A few verses in praise of the Medical Corps end as follows:

"But, here's to the man of the R. A. M. C.,
Buzzing about on the field like a bee,
Tending the wounded where lead's flying hot,
Biting his lip when he gets hisself shot;
Brave as the best of us, hurt and not tell,
Doctor he may be — he's soldier as well."

MEDICAL NOTES.

THE GALLINGER BILL. — Certain changes have been made in the Committee on the District of Columbia, relative to Senator Gallinger's bill for the "Further Prevention of Cruelty of Animals in the District of Columbia." The Committee, as it now stands, consists of Senator James McMillan, Michigan, Chairman, and Senators J. H. Gallinger, New Hampshire; H. C. Hansborough, North Dakota; R. Redfield Proctor, Vermont; J. C. Pritchard, North Carolina; Lucien Baker, Kansas; George L. Wellington, Maryland; S. R. Mallory, Florida; W. V. Sullivan, Mississippi; W. A. Clark, Montana; Thomas S. Martin, Virginia; Wm. M. Stewart, Nevada; and Richard Kenney, Delaware. Personal letters may be addressed to them or to other senators. Petitions should be addressed to the Senate of the United States. For details regarding this bill, see Dr. W. W. Keen's letter in our issue of December 21, 1899.

SMALL-POX IN KENTUCKY. — It is reported that small-pox is prevalent in five counties of the State, and the State Board of Health is without money to meet the epidemic. Resignations of the county boards of health in about a dozen counties in which the disease is the most serious have been received. The cause of these resignations is the lack of money with which to combat the disease. Daily requests for inspectors come from other counties where small-pox undoubtedly exists, but the State Board has no money to send the inspectors, and county authorities refuse to take any action.

THREE CENTENARIANS. — It is reported that Mrs. Phebe D. Hedges, who recently died in New Jersey, was one hundred years and six months old. Her father was a minute man in the Revolution. Mrs Sarah Weed, of Merrimac, Mass., it is claimed, has reached the age of one hundred and two years, and still finds herself interested in passing events. Mrs. Ellen Callahan, a native of County Cavan, Ireland, died in New York on January 22d, at the age of one hundred and one years.

BUBONIC PLAGUE AT ROSARIO AND HONOLULU. — The Argentine Government has issued a decree acknowledging the existence of bubonic plague at Rosario. The Government has decided to isolate the town from the rest of the country. It is announced that Major Taylor, at Honolulu, reports under date of January 15th, that there have been 34 cases of bubonic plague and 27 deaths in Honolulu, and that the situation is serious.

DIED OF A BROKEN HEART (?). — The somewhat extraordinary statement is made that a horse, suddenly separated from his mate, refused food and finally died four days afterwards. The autopsy showed a ruptured heart, from which it is assumed the lesion resulted from the emotional disturbance incident upon the separation. Apart from this doubtful relation of cause and effect, the lesion is of considerable interest.

WIRE-CUTTING PLIERS FOR THE BRITISH ARMY. — A soldier at the front, in writing to a friend, has suggested the desirability of having a limited number of wire-cutting pliers issued to the troops, for the purpose of quickly cutting through barbed wire entanglements while under fire. The experience of the United States Army during the operations about Santiago might have forestalled this criticism.

NO YELLOW FEVER AT ORIZABA. — Cases of so-called yellow fever at Orizaba, Mexico, have been investigated by the Board of Health of the State of Vera Cruz, and they report that the disease is not yellow fever, but an acute form of malarial fever. Nearly 35 per cent. of the cases have been fatal.

FLEAS AND PLAGUE. — It is reported from Sydney, N. S. W., that a man has been infected with plague, probably by inoculation through the bite of a flea.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, January 31, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 93, scarlatina 61, measles 53, typhoid fever 6.

NEW OUT-PATIENT BUILDING FOR CARNEY HOSPITAL. — For a long time the building used as an out-patient department by the Carney Hospital has been inadequate to the increasing demands made upon it. Ground has been purchased in the neighborhood of the hospital, on which it is hoped to erect a substantial four-story brick building, about 51.85 by 55.38 feet, and arranged for ten clinics, with all the necessary facilities for the staff. The money necessary for this project must be raised in part by subscription; $10,000 has been appropriated by the Legislature, under the condition that an equal amount be provided by those in charge of the institution.

NEW BUILDINGS FOR BOARD OF HEALTH HOSPITALS FOR BROOKLINE, MASS. — It is desired to improve the Board of Health Hospitals in the town of Brookline, that they may be able to meet the exigencies of a possible epidemic. The plan is to have three new buildings erected in the southern part of the town on the site of the old buildings.

A NEW MORGUE FOR BOSTON. — The contract for the building of a new and much-needed city morgue on North Grove Street has been awarded, and the work of construction will begin at once. The appropriation amounts to $9,000.

NEW YORK.

A CASE OF AMNESIA. — In the JOURNAL for October 6, 1898, a notice of an interesting case is given, in which a Norwegian, as a result of an injury to the brain, for which he was treated at St. Vincent's Hospital, New York, entirely forgot his native language, although he was able to speak with some difficulty in English. Since then the man has been living in New London, Conn., and a recent account of him published in the newspapers states that he has never regained the use of Norwegian, and that, although in a normal condition in other respects, he still has absolutely no memory of events occurring or persons met with previous to his accident.

ERYSIPELAS AT AN INFIRMARY. — Several cases of erysipelas having appeared in the wards of the S. R. Smith Infirmary, at New Brighton, Staten Island, the principal hospital in the Borough of Richmond, and ordinary methods having failed to check the spread of the disease, the medical staff have determined to isolate all the erysipelas patients in the contagious wing of the hospital. Consequently it has been necessary to give notice that no more cases of diphtheria or other contagious disease can be received at the institution for the present, and hospital cases of this character will have to be taken to Manhattan or Brooklyn for treatment.

A BOOK ON MUNICIPAL GOVERNMENT. — Announcement is made that Mr. Bird S. Coler, Controller of the City of New York, is about to publish an important work entitled "Municipal Government," in which he will set forth the practical working of the new charter as regards the various city departments, and point out such defects in the charter as have shown themselves in its administration. It is understood that in it he devotes much attention to the water supply, present and future, and to a discussion of municipal charities and of private charitable institutions, and their relations to the public and to the City Government.

A BEQUEST TO CORNELL. — The twentieth annual dinner of the Cornell University Alumni Association, of New York, was held on January 26th. The guest of honor was Dr. Jacob Guild Schurman, President of the University, and in the course of his remarks he announced that an anonymous gift of $80,000 had recently been received for the erection of a building devoted to the study of anatomy and physiology.

ARMY NOTES.

STUDY OF TROPICAL DISEASES IN THE PHILIPPINES. — By direction of the Secretary of War, a board of medical officers, consisting of Lieutenants Richard H. Strong and William J. Calvert, assistant surgeons, and Acting Assistant Surgeon Joseph J. Curry, United States Army, has been appointed to meet at one of the general hospitals near Manila, Philippine Islands, for the purpose of studying tropical diseases as they occur in those islands. The board is to receive its instructions from the Surgeon-General and will be under the immediate direction of the chief surgeon at Manila. Drs. Strong and Calvert are graduates of Johns Hopkins University Medical Department, and have devoted considerable time to the study of pathology and bacteriology. Dr. Curry has been in the service since the outbreak of the war with Spain and has served as pathologist and bacteriologist at Chickamauga Park and at the general hospitals at Fort Myer, Va., Savannah, Ga., and Manila, P. I. He was formerly attached to the pathological department of the Boston City Hospital.

DENTISTS AND VETERINARIANS FOR THE ARMY. — Strong efforts are being made to induce congressional action establishing a corps of dental surgeons in the military establishment. The latest proposal is to appoint a dental surgeon with the rank of major to each 1,000 men. As the grade of major is attained by the army medical officer only after eighteen or twenty years' service, it is scarcely possible that any such discrimination in favor of dental surgeons will be made. The services of dentists are much needed by troops serving on foreign stations and it is probable that Congress will authorize the hiring of competent men to satisfy this need, under the same regulations as those under which contract surgeons are now employed. It is also urged that veterinary surgeons should be admitted as commissioned officers. The plan is said to be opposed by Surgeon-General Sternberg and Adjutant-General Corbin.

FORT BAYARD HOSPITAL FOR TUBERCULOSIS. — The post of Fort Bayard, New Mexico, has been discontinued as a military station for troops and all the buildings pertaining thereto have been turned over to the Surgeon-General for use in connection with the general hospital at that post, established for the treatment of pulmonary tuberculosis occurring in officers and enlisted men of the army. We have already had occasion to refer editorially to this action of the War Department as a needed and most desirable means of increasing the efficiency of the medical service.

Miscellany.

PRECAUTIONS AGAINST THE IMPORTATION OF PLAGUE.

WE learn from the *Lancet* that the Local Government Board for Scotland, in a circular letter dated January 15, 1900, again calls the attention of local sanitary authorities to the presence of plague in Portugal and the necessity for carrying out "with especial care" the measures in force in these islands for preventing the importation of infection. Their notice is specially directed to a general order issued by the Commissioners of Customs on October 31st of last year. The object of that order was "to make certain that in carrying out the regulations of the Board the

medical officer of health shall receive the greatest possible assistance from officers of customs," and it is pointed out that, on one occasion at least, such assistance was actually declined by an inspector of customs. The mechanism adopted for joint action by the medical officer of health and customs officials for dealing with arrivals from infected ports is briefly as follows: The officers of customs look to the medical officer of health to inform them from time to time of any particular ports or countries, the vessels arriving from which he would desire to visit. In this connection it is pointed out in the letter of the Board that "the earliest information which would usually be available to this end is that which would be obtained by a regular examination of the news telegraphed from abroad for the purposes of the daily press. On the other hand, the officers of customs will, in their turn, give the medical officer of health any information which they may possess respecting the arrival or impending arrrival of any ships from the ports or countries in question. The term "medical officer of health," it may be noted, includes any duly qualified medical practitioner appointed or employed by a local authority to act in the execution of the orders relating to plague. Attention is also drawn to the possibility of the infection of plague being carried by some of the lower animals, and especially by "rats, mice, and, by natural sequence, cats," and the necessity for inquiring into the evidences of disease in these animals and taking measures for destroying them if occasion should arise. That rats can and do suffer from plague and are an important means of diffusing infection appears no longer to admit of doubt. The susceptibility of mice appears to be very much less marked, and these animals would seem to be far less active agents in the spread of plague than rats. There is, however, evidence that they can aid in spreading the disease and it is believed that they did so to some extent in Formosa, in Jeddah, in Alexandria, and perhaps elsewhere. Cats, the third group of animals mentioned, appear to be even less susceptible than mice. Scattered samples of what have been believed to be attacks of plague in cats have been published from Poona Worlee, Jawalapur and elsewhere in India, and from Hong Kong, Jeddah, Mongolia, Hoihow, Mauritius and Oporto; but it is perhaps open to question whether in any instance there has been scientific proof that the animals have in truth suffered from the plague.

THE DISCOVERY OF SCABIES.

ALTHOUGH, as far back as the twelfth century, Avenzoar described a disease of the skin characterized by the presence beneath the epidermis of animalculæ resembling lice, so small as scarcely to be visible, which, he remarked, could be extracted by scratching the skin, the disease now universally known as scabies was, even as recently as this century, regarded as a constitutional affection associated with cachexia and inflammation. It appears, however, that Rabelais, who, though a doctor of medicine, is better known as a political writer than as a physician, was well acquainted with the disease, and was perfectly cognizant of its nature, contagiousness and treatment. It is narrated indeed in his famous work that one of the ancestors of Pantagruel was "exceedingly expert in removing worms from the hands," and elsewhere Rabelais laments the death of a medical friend who died in consequence of his having accidentally wounded himself in removing one of these worms with a paper knife. The re-discovery of itch in France dates from 1835, when a medical student demonstrated to Alibert, incredulous, how in his native land of Corsica the peasants withdrew the parasite by the aid of a needle, a feat which he repeated in Alibert's clinic. In a recent monograph on the subject it is shown that the disease has been discovered and re-discovered some half-dozen times, at intervals of centuries. How often is this the case with medical discoveries? The worst of it is that treatments which have been again and again discovered and dismissed as useless or injurious are from time to time once more brought forward only to excite and cause fresh disappointment. If contemporary discoverers would only take the trouble to consult Neale's Digest or the *Index Medicus* before launching their fancied innovations, they would often be dissuaded from encumbering medical literature with their "mare's nests." — *Medical Press.*

TYPHOID INOCULATIONS.

AN interesting article by Dr. A. E. Wright and Major W. B. Leishman, professor and assistant professor of pathology at the Army Medical School, Netley, on the results which have been obtained by the anti-typhoid inoculations and on the methods employed in the preparation of the vaccine may be found in the *British Medical Journal*, January 20th. Of 2,835 men inoculated in India from a force of about 11,000 troops, and a large proportion of those inoculated were unseasoned recruits especially prone to typhoid, only 27, or .95 per cent., took typhoid fever and only 5, or .2 per cent., died, whilst of 8,460 uninoculated men, many of whom had passed safely through previous exposure, 213, or 2.5 per cent, contracted the disease, and 23, or .34 per cent., died. These observers are inclined to the belief that the protection of inoculation may last at least eighteen months, and that the type of disease when contracted after inoculation is perhaps a mild one.

The conditions for keeping and preparing the material for inoculation were not in all respects favorable, otherwise possibly even better results might have been obtained.

Correspondence.

ASEPTIC MILK.

AUGUSTA, ME., January 23, 1900.

MR. EDITOR: — At the suggestion of the municipal authorities of Augusta, Me., I began in June, 1899, an investigation of the milk supply of that city, and some facts and conclusions arrived at by myself and co-workers, as set forth in my report, may be of interest to the profession.

That milk is an almost perfect culture medium for all pathogenic bacteria, and consequently should be handled under well-studied antiseptic precautions, is a fact well known but too much ignored by the profession which aims at saving life, especially in smaller cities and villages. Milk occupies on our diet list a unique position, for several reasons: (1) It contains no refuse matter; (2) It contains members of all the essential food elements, namely: Albu-

mins are represented by casein and lactalbumin, which amounts on an average in 100 specimens examined by the writer to 3.4 per cent. Fats are represented by butter fat, about 3.7 per cent.; while the hydrocarbons are represented by milk sugar, averaging 4.7 per cent.; lastly, we have in the "ash" the inorganic salts. It occupies a unique position for another very important reason, in that it is practically the only food staple taken into the stomach unsterilized by cooking, and no food needs sterilization more.

Ernest Finchman, of London, makes a statement, as he says, largely on theoretical grounds, that "milk immediately taken from the cow's udder contains no bacteria, but before it is fairly settled in the pail it contains more than 10,000 to the cubic centimetre." I must record a different result from my observations, for in every instance where, under the strictest antiseptic precautions, I have withdrawn milk from the cow, I have found bacteria of various kinds; most conspicuous were "bacillus coli communis," which could not have come from outside contamination. My method of "milking" was as follows: The udder was rendered as nearly surgically clean as soap, alcohol, permanganate of potash, and corrosive sublimate would render it; then a sterilized silver canula with a sterilized rubber tube attached, with the distal end closed, was inserted into the udder. The milk was allowed to run for two minutes, and then a portion was received into sterilized flasks, and cultures made immediately. Some of the bacteria found were non-pathogenic, such as the oidium lactis, but in one specimen tubercle bacilli were clearly demonstrated, and in several the bacillus coli communis. I will not here enumerate all the varieties found by the tests.

There is nothing surprising in finding bacteria in the milk ducts, when we stop to consider that the udder is by no means an hermetically sealed part. Bacteria of any sort which happen to be in contact readily gain access and follow up the lacteal ducts even to the minute ramification of the milk gland. If the gentle bovine happens to be wading in a swamp, or lying in a dung heap, both of which customs she is prone to indulge in at favoring opportunities, her flanks, hair and udders, of course, swarm with bacteria. Certain micro-organisms, for instance, that which produces lactic acid fermentation and those which determine the color of milk, exist normally in the milk. The oidium lactis may be well likened to the yeast germ, and in itself is equally harmless, as are also the parachromophoric bacteria whose products color the milk. If the normally existing bacteria in milk were all that we had to deal with, fewer children would die with cholera infantum, ileocolitis and other zymotic diseases.

Probably the one bacillus giving us the most trouble is bacillus coli communis, which, as is well known, exists normally in the colon of all warm-blooded animals, and when existing to excess gives us diarrhea, dysentery, ileocolitis, cholera infantum, or perhaps only chronic intestinal indigestion of a milder degree. It is vastly different to possess a small, or we might say a normal, number of these bacteria in the intestine, or have an excess of the same. The animal economy can cope safely with a certain amount of poison, or a certain number of bacteria, but beyond this point, differing as to the "vital resistance," we may not go with impunity.

Were it possible for all infants brought up on artificial food to receive at all times a supply of cows' milk which was free from putrefactive and pathogenic bacteria, a result would be obtained beside which all other sanitary and hygienic improvements of the past half century would seem insignificant.

Leipsic, in a paper presented to the Düsseldorf Congress in Berlin, gives the following résumé: "The continuous use of milk sterilized by heat by infants leads to a large number of cases of impaired digestion and nutrition, anemia, rhachitis and scurvy, and in any case a predisposition to any and all infections." Of refrigeration nothing need be said, except that only during continuance of the low temperature a slight retarding of the development of bacteria is accomplished. The sterilization of milk by chemical means as it has been practised by milkmen, dairymen and "contractors," has been very crude and faulty. Good reason for objections to the use of boracic acid, bicarbonate of sodium and salicylic acid exists, based on clinical and laboratory experimentation. The one agent, bicarbonate of sodium, which appears perhaps the most harmless is by no means the least harmful, though in itself non-toxic. It is a very feeble germicide, but what it accomplishes in milk which gives a false sense of security is to neutralize the acids produced by fermentation, while not retarding the development of the germs which produce the acids. In other words, it puts a mask on the milk, so that it does not present the gross badness with which we associate decomposition, while at the same time all sorts of bacteria may be swarming in the fluid. Boracic acid, more germicidal and also practically non-toxic, when in milk in sufficient amount to prevent development of bacteria, also has an inhibitory effect on the digestive enzymes. Salicylate of sodium has a place in our armamentarium, but it is removed from the dairy and kitchen, for the same reasons that apply to boracic acid.

There has recently been brought forward by Reinhardt, of Berlin, a chemical which combines some very valuable properties, hitherto uncombined in any other single substance. To it he gives the chemical name "iso-ethyline!" It is formed something after the manner of formaldehyde, that is, by destructive distillation of ethylic alcohol. While it possesses some of the characters of formaldehyde it is lacking in other essentials. The exact architecture of the chemical equation is still a matter of doubt, though the properties have been studied for two or three years. It is volatile at temperatures above 100° F. Its germicidal action is slightly less than formaldehyde. It responds feebly to the ferric-chloride test for formaldehyde, as do two or three other analogous bodies. I have recently made some experiments with it on animals, and cannot learn that it inhibits digestion in strengths sufficient to entirely stop development of bacteria in milk and bouillon. It is effectual only during its presence, and this in part explains the reason that it has no inhibitory action on digestion, for the body temperature is sufficient to at once volatilize it.

Even though this substance "iso-ethyline" possess all the advantages we hope for it, it will be looked upon with some doubt, because many of the chemical agents hitherto used in milk are in disrepute, and for good reasons. It would seem from some recent experiments that we were nearing the proper solution of the "antiseptic milk" question. It is certainly a subject worthy of the most careful study and research, and anything new which bears upon the subject should be given to the profession.

Very truly yours,
G. M. RANDALL, M.D.

METEOROLOGICAL RECORD

For the week ending January 20th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 3,015; under five years of age 1,008; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping-cough, erysipelas, fevers and consumption) 565, acute lung diseases 593, diphtheria and croup 128, measles 50, typhoid fever 43, scarlet fever 27, whooping-cough 19, cerebrospinal meningitis 19, diarrheal diseases 17, erysipelas 14.

From scarlet fever New York 13, Boston 6, Philadelphia 4, Cambridge 2, Washington and Worcester 1 each. From whooping-cough New York 11, Philadelphia and Baltimore 2 each, Boston, Nashville, Fall River and Chelsea 1 each. From cerebrospinal meningitis New York and Worcester 4 each Somerville and Gloucester 2 each, Boston, Baltimore, Washington, Providence, Lynn and Amesbury 1 each. From diarrheal diseases Fall River 4, Providence 3, New York, Philadelphia, Pittsburg and Nashville 2 each, New Bedford 1. From erysipelas New York 7, Boston 3, Philadelphia 2, Baltimore and Lowell 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,236, for the week ending January 13th, the death-rate was 20.1. Deaths reported 6,074: acute diseases of the respiratory organs (London) 994, measles 142, whooping-cough 105, diphtheria 89, fever 56, diarrhea 31, scarlet fever 27, small-pox (Hull) 3.

The death-rates ranged from 15.6 in Burnley to 44.9 in Nottingham: Birmingham 33.6, Bradford 20.0, Bristol 20.1, Gateshead 22.4, Hull 22.3, Leeds 21.5, Liverpool 34.6, London 33.3, Manchester 23.0, Newcastle-on-Tyne 22.0, Sheffield 25.5, West Ham 22.2.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JANUARY 27, 1900.

H. N. T. HARRIS, surgeon, ordered to the "Albany" *via* the "Prairie."

L. L. VON WEDEKIND, passed assistant surgeon, ordered to duty on the "Richmond."

(CHANGE BY CABLE FROM ASIATIC STATION.)

R. C. HOLCOMB, assistant surgeon, detached from the "Solace" and ordered to the "Helena."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING JANUARY 25, 1900.

WILLIAMS, L. L., surgeon. Granted extension of leave of absence for ten days. January 23, 1900.

PETTUS, W. J., surgeon. Granted leave of absence for one month and twenty-nine days from February 10th. January 22, 1900.

PARKER, H. B., assistant surgeon. Directed to report at Washington, D. C., for special temporary duty. January 23, 1900.

FRICK, JOHN, acting assistant surgeon. Granted leave of absence for thirty days from February 28th. January 25, 1900.

BOARD CONVENED.

Board convened to meet at 378 Washington Street, New York, N. Y., on Wednesday, February 7, 1900, for the purpose of examining candidates for appointment as assistant surgeons in the Service. Detail for the Board; Surgeon H. W. AUSTIN, Chairman; Surgeons C. E. BANKS and L. L. WILLIAMS, Recorder.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday, February 5th, at 8 o'clock.

Subject: "Splenic Anemia." Dr. James M. Jackson will open the discussion with a short paper and report of a case. Drs. F. C. Shattuck, Hewes, Morse, Wentworth, Fitz and others will report cases. Any member having a case is urged to be present and report it.

Dr. Jas. S. Stone will read a paper entitled, "Injury to the Shoulder-joint at Birth."

ARTHUR K. STONE, M.D., *Secretary*, 657 Boylston Street.

SUFFOLK DISTRICT MEDICAL SOCIETY, SURGICAL SECTION. — The Surgical Section will meet at the Medical Library, 19 Boylston Place, on Wednesday evening, February 7, 1900, at 8.15 o'clock.

Papers: "The Operative Surgery of the Knee-joint for other than Tubercular Disease," by Dr. J. E. Goldthwait.

"Varieties of Bacteria in Abdominal Infections," by Dr. Daniel Fiske Jones.

F. G. BALCH, M.D., *Secretary*, 279 Clarendon St.

MASSACHUSETTS MEDICO-LEGAL SOCIETY. — A regular meeting will be held on Wednesday, February 7th, at the Medical Library, 19 Boylston Place, at 1 o'clock, P. M.

The following papers will be read:

"Declarations of Persons Immediately Preceding Death," by District Attorney M. J. Sughrue.

"The Marks Produced by Pistol Shots," by Dr. G. deN. Hough.

"A Case of Extra-uterine Pregnancy," by Dr. F. Holyoke.

Members of the medical profession are cordially invited.

JULIAN A. MEAD, M.D., *Secretary*.

NATIONAL PURE FOOD AND DRUG CONGRESS. — The third annual meeting of this Association will be held in Washington, D. C., beginning Wednesday, March 7, 1900.

RESIGNATION.

CHARLES G. CUMSTON, M.D., has resigned his position of professor of surgical pathology in the Tufts College Medical School.

RECENT DEATHS.

CLARA COOLIDGE WILLIAMS, relict of the late Dr. Lewis Williams and aunt of Dr. Roswell Park, of Buffalo, died in Pomfret, Conn., January 22d, aged eighty years, one month and twenty-nine days.

JOHN CARGILL SHAW, M.D., professor of diseases of the nervous system at the Long Island College Hospital, Brooklyn, died on January 23d, of pneumonia, resulting from influenza. He was fifty-five years of age, and was born in the Island of Jamaica, West Indies. He was graduated from the College of Physicians and Surgeons, New York, in 1874. Having won distinction as a specialist in nervous diseases he was appointed superintendent of the Kings County Insane Asylum, where, by the introduction of modern methods, he revolutionized the treatment previously in vogue there. Later he returned to private practice and was successively elected president of the New York Neurological Society, the Kings County Medical Society and the Pathological Society. At the time of his death he was consulting neurologist to the Kings County Hospital, St. John's Hospital, St. Catherine's Hospital and other Brooklyn institutions.

WILLIAM S. HOUSE, M.D., a prominent physician of Rockland County, N. Y., died at his home in Haverstraw, on the Hudson, on January 27th, of apoplexy. He was in the sixty-third year of his age.

BOOKS AND PAMPHLETS RECEIVED.

Report of the Commissioner of Education for the Year 1897-98. Vol. II.

Ueber Tanocol, ein neues Darmadstringens. Von Dr. Goliner, Erfurt. 1899.

Twentieth Annual Report of the Associated Charities of Boston, November, 1899.

Refraction and How to Refract, including Sections on Optics, Retinoscopy, the Fitting of Spectacles and Eyeglasses, etc. By James Thorington, A.M., M.D., Adjunct Professor of Ophthalmology in the Philadelphia Polyclinic and College for Graduates in Medicine, etc. Philadelphia: P. Blakiston's Son & Co. 1900.

Bacteria, Especially as they are Related to the Economy of Nature, to Industrial Processes and to the Public Health. By George Newman, M.D., F.R.S. (Edin.), D.P.H. (Camb.), etc., Demonstrator of Bacteriology in King's College, London. Illustrated. New York: G. P. Putnam's Sons. London: John Murray. 1899.

The Dispensatory of the United States of America. By George B. Wood, M.D., and Franklin Bache, M.D. Eighteenth edition, thoroughly revised and largely rewritten, with illustrations. By H. C. Wood, M.D., LL.D., Joseph P. Remington, Ph.M., F.C.S., and Samuel P. Sadtler, Ph.D., F.C.S. Philadelphia: J. B. Lippincott Co. 1899.

Two Lectures on the Temples and Ritual of Asklepios at Epidaurus and Athens, delivered at the Royal Institution of Great Britain. By Richard Caton, M.D., F.R.C.P., Honorary Physician, Liverpool Royal Infirmary: Emeritus Professor of Physiology, University College, Liverpool. Reprinted from "Otia Merseiana." 1899.

A Text-Book of Materia Medica, Therapeutics and Pharmacology. By George Frank Butler, Ph.G., M.D., Professor of Materia Medica and Clinical Medicine in the College of Physicians and Surgeons, Medical Department of the University of Illinois, etc. Third edition, thoroughly revised. Philadelphia: W. B. Saunders. 1899.

A Contribution to the Surgery of Fractures and Dislocations of the Upper Extremity, based upon an Analysis of about Seven Hundred Consecutive Cases Observed at the Manchester Royal Infirmary. By J. E. Platt, M.S. (Lond.), F R.C.S., Honorary Surgeon to the Hulme Dispensary, etc. Illustrated by 23 drawings and skiagrams. London: H. K. Lewis. 1899.

Precautions against Small-pox. Precautions to be Adopted by Funeral Directors to Prevent the Spread of Contagious and Infectious Diseases, including the Law establishing a State Board of Undertakers. Precautions against the Plague. Laws for the Better Protection of Life and Health, passed by the Legislature of 1897. Pennsylvania Board of Health.

Treatise on Orthopedic Surgery. By Edward H. Bradford, M.D., Surgeon to the Children's Hospital and to the Samaritan Hospital; Assistant Professor of Orthopedic Surgery, Harvard Medical School, and Robert W. Lovett, M.D., Assistant Surgeon to the Children's Hospital; Surgeon to the Infants' Hospital. Second revised edition. New York: William Wood & Co. 1899.

Saunders' Question-Compends, No. 11: Essentials of Diseases of the Skin, including the Syphilodermata, arranged in the Form of Questions and Answers prepared especially for Students of Medicine. By Henry W. Stelwagon, M.D., Ph.D., Clinical Professor of Dermatology in the Jefferson Medical College, etc. Fourth edition. Philadelphia: W. B. Saunders. 1899.

System of Diseases of the Eye. By American, British, Dutch, French, German and Spanish authors. Edited by William F. Norris, A.M., M.D., and Charles A. Oliver, A.M., M.D., Philadelphia, Pa. Volume IV. Motor Apparatus, Cornea, Lens, Refraction, Medical Ophthalmology. With 51 full-page plates and 211 text illustrations. Philadelphia and London: J. B. Lippincott Co. 1900.

Bacteriology in Medicine and Surgery, a Practical Manual for Physicians, Health Officers and Students. By Wm. Hallock Park, M.D., Associate Professor of Bacteriology and Hygiene, University and Bellevue Hospital Medical College, etc., assisted by A. R. Guerard, M.D., Assistant Bacteriologist, Department of Health, City of New York. New York and Philadelphia: Lea Brothers & Co. 1899.

Practical Anatomy, including a Special Section on the Fundamental Principles of Anatomy. Edited by W. T. Eckley, M.D., Professor of Anatomy in the College of Physicians and Surgeons, University of Illinois, etc., and Mrs. Corinne Buford Eckley, Instructor in Anatomy in the Northwestern University Dental School, etc. With 347 illustrations, many of which are in colors. Philadelphia: P. Blakiston's Son & Co. 1899.

Deaver's Surgical Anatomy: A Treatise on Human Anatomy in its Application to the Practice of Medicine and Surgery. By John B. Deaver, M.D., Surgeon-in-chief to the German Hospital, Philadelphia. In three volumes, illustrated by about 400 plates, nearly all drawn for this work from original dissections. Vol. I. Upper Extremity, Back of Neck, Shoulder, Trunk, Cranium, Scalp, Face. Philadelphia: P. Blakiston's Son & Co. 1899.

Retinoscopy (or Shadow Test) in the Determination of Refraction at One Metre Distance with the Plane Mirror. By James Thorington, M.D., Adjunct Professor of Diseases of the Eye in the Philadelphia Polyclinic and College for Graduates in Medicine; Assistant Surgeon to Wills Eye Hospital, etc. Third edition, revised and enlarged, 43 illustrations, 12 of which are colored. Philadelphia: P. Blakiston's Son & Co. 1899.

Saunders' Question-Compends, No. 4: Essentials of Medical Chemistry, Organic and Inorganic, containing also Questions of Medical Physics, Chemical Philosophy, Analytical Processes, Toxicology, etc., prepared especially for Students of Medicine. By Lawrence Wolff, M.D., Demonstrator of Chemistry, Jefferson Medical College, etc. Fifth edition, thoroughly revised by Smith Ely Jelliffe, M.D., Ph.D. Philadelphia: W. B. Saunders. 1899.

Lea's Series of Pocket Text-Books. Physiology: A Manual for Students and Practitioners. By Howard D. Collins, M.D., Assistant to the Attending Surgeon of the Roosevelt Hospital, etc., and Wm. H. Rockwell, Jr., M.D., Assistant Demonstrator of Anatomy, College of Physicians and Surgeons (Columbia University), New York, etc. Series edited by Bern B. Gallandet, M.D. Illustrated. Philadelphia and New York: Lea Brothers & Co. 1899.

Lectures upon the Principles of Surgery, delivered at the University of Michigan. By Chas. B. Nancrede, A.M., M.D., LL.D., Professor of Surgery and Clinical Surgery, Emeritus Professor of General and Orthopedic Surgery, Philadelphia Polyclinic, etc. With an appendix containing a Résumé of the Principal Views held concerning Inflammation. By Wm. A. Spitzley, A.B., M.D., Senior Assistant in Surgery, University of Michigan. Illustrated. Philadelphia: W. B. Saunders. 1899.

Gout: Its Pathology and Treatment, founded on the Goulstonian Lecture on "The Chemistry and Pathology of Gout," delivered by the author before the Royal College of Physicians of London in 1897; with the addition of some Recent Investigations Concerning the Treatment of Gout and a Detailed Account of the Treatment of the Various Forms of Gout. By Arthur P. Luff, M.D. (Lond.), B.Sc., F.R.C.P., Physician in charge of Out-Patients and Lecturer on Forensic Medicine at St. Mary's Hospital. New York: Wm. Wood & Co. 1899.

A Manual of Organic Materia Medica and Pharmacognosy: An Introduction to the Study of the Vegetable Kingdom and the Vegetable and Animal Drugs. etc. By Lucius E. Sayre, B.S., Ph.M., Dean of the School of Pharmacy, Professor of Materia Medica and Pharmacy in the University of Kansas, etc. Second edition, revised, with Histology and Microtechnique by William C. Stevens, Professor of Botany in the University of Kansas. With 374 illustrations, the majority of which are from original drawings. Philadelphia: P. Blakiston's Son & Co. 1899.

The International Text-Book of Surgery. By American and British authors. Edited by J. Collins Warren, M.D., LL.D., Professor of Surgery in Harvard Medical School; Surgeon to the Massachusetts General Hospital, and A. Pearce Gould, M.S., F.R.C.S., Surgeon to the Middlesex Hospital; Lecturer on Practical Surgery and Teacher of Operative Surgery, Middlesex Hospital Medical School; Member of the Court of Examiners of the Royal College of Surgeons, England. Vol. I. General and Operative Surgery. With 458 illustrations in the text and nine full-page plates in colors. Philadelphia: W. B. Saunders. 1899.

Progressive Medicine: A Quarterly Digest of Advances, Discoveries and Improvements in the Medical and Surgical Sciences. Edited by Hobart Amory Hare, M.D., Professor of Therapeutics and Materia Medica in the Jefferson Medical College, Philadelphia; Physician to the Jefferson Medical College Hospital; Member of the Association of American Physicians, etc. Volume II, June, 1899. Surgery of the Abdomen, including Hernia; Gynecology; Diseases of the Blood; Diathetic and Metabolic Disorders; Diseases of the Spleen, Thyroid Gland and Lymphatic System; Ophthalmology. Philadelphia and New York: Lea Brothers & Co. 1899.

Original Articles.

THE MASSACHUSETTS STATE HOSPITAL FOR CONSUMPTIVES AT RUTLAND; ITS PURPOSE AND THE WORK ACCOMPLISHED DURING THE FIRST YEAR.[1]

BY VINCENT Y. BOWDITCH, M.D., BOSTON.

In the spring of 1895 the Massachusetts State Legislature, upon the suggestion of physicians and members of the city, appropriated a sum of money for the establishment of a hospital, or sanitarium, for the treatment of consumptives in a suitable location in the State.

The hilly region of central Massachusetts, in the town of Rutland, about twelve miles northwest of Worcester, was wisely selected by the Board of Trustees, and in October, 1898, Governor Wolcott formally declared the institution to be ready to receive patients.

This event marked an epoch in the treatment of tubercular disease in our country, inasmuch as it was the first legislative attempt in the United States to cope with consumption and other diseases of tubercular origin.

The sanitarium treatment of phthisis has become an old story to most of us, but until comparatively recently in this country, institutions have been established by private individuals only, and usually for the well-to-do classes, the exceptions being, so far as I know, Dr. Trudeau's Adirondack Sanitarium, the Sharon Sanitarium and another small one at Aiken, S. C., recently established under Dr. C. F. McGahan's supervision, all intended for people of very limited means. I am speaking of sanitaria for incipient cases, not of hospitals for the hopelessly sick.

In the original prospectus of the Rutland Hospital, or Sanitarium, as it should more properly be termed, the trustees use the following words: "Inasmuch as the primary purpose of the hospital is to arrest the disease, and if possible to extirpate it, only such patients will be admitted as are deemed not too far advanced to admit of reasonable hope of radical improvement. In no sense is the hospital to be considered as a home for the hopelessly sick; for, great as is the recognized need for homes of refuge for advanced consumptives, such service is manifestly incompatible with the even more needed service of rescuing lives that can be saved only by sanitarium treatment."

The results of the first year's work are of special interest, therefore, from the fact that they show what can be done for people of very limited means, even in the harsh climate of New England, which is considered so unfavorable for consumptives.

The hospital stands upon the southern slope of a hill about a mile and a half from the village of Rutland, at an altitude of about 1,200 feet. It is protected on the northwest by a thick forest of pine, hemlock and hard wood, overlooking the rolling country of the centre of our State, Mt. Wachusett being about eight miles to the north. The water supply comes from Muschopauge Lake, near by, and the sewage is disposed of by means of large filter beds on the northern slope of the hill, about a mile distant. The buildings are arranged as pavilion wards, one story in height, spreading like the outstretched fingers of the hand towards the south from a long convex corridor which connects the buildings; the kitchen, heating, electrical and laundry departments being all towards the northern side of the institution. The patients sleep in open wards as a rule, a few small isolated rooms being used chiefly in case of severe illness or for special reasons only. Sun-rooms and piazzas are placed at the ends of the wards, the whole arrangement throughout being such as to obtain the maximum of both sunlight and fresh air. For winter use, small temporary wooden shelters are erected, open only towards the south, where patients take daily and hourly air baths. In the neighboring wood, as picturesque and useful adjuncts to the hospital, are the various camps made by the patients from boughs and other material and here much of the daytime is passed both in summer and winter.

At the outset many cases of advanced pulmonary disease were admitted for whom there was very little hope of anything other than temporary improvement. The large number of applications since that time has justified the more careful selection of cases in order that those with really incipient disease may have the benefit of the treatment. By this decision we believe we accomplish the greatest good to the greatest number.

From October 10, 1898, to October 1, 1899, the number of patients who were admitted to my service was	212
Number re-admitted	2
Total number of admissions	214
Number discharged up to October 1, 1899	126
Number still under treatment October 1, 1899	88
	214
Of the 126 discharged, the number who remained less than two weeks and are therefore not considered in the results is	11
The number who remained more than two weeks is (Of these one was a case of bronchitis only.)	115
	126
Of the remainder (114), the number discharged as "arrested cases" is	35
Number "much improved"	37
Number "improved," including one case of tubercular disease of the bladder, without pulmonary disease	17
Number "not improved," including those who failed and returned to their homes or were sent to other hospitals	24
Number "well," bronchitis only	1
Number died in the hospital[2]	1
	115

SYNOPSIS OF "ARRESTED CASES."

Of these the number having bacilli in their sputa previous to or after entrance	20
The number of cases without sputa on whom the tuberculin test was tried with positive result	2
The number of cases having undoubted symptoms and physical signs of pulmonary disease *without bacilli*. (Tuberculin test not used.)	9
The number of cases having very suspicious symptoms without definite signs in the chest (cough, malaise, slight fever, loss of flesh, etc.). (Tuberculin test not used.)	4
	35

In my nomenclature I have differed from some of my colleagues for the following reason: By the use of the term "arrest of disease," I have adhered to the custom which I have followed at the Sharon Sanitarium for several years, as being on the whole to me the simplest method of describing those cases in which all active symptoms, like cough, expectoration and fever, have disappeared and where the general symptoms would seem to indicate a complete restora-

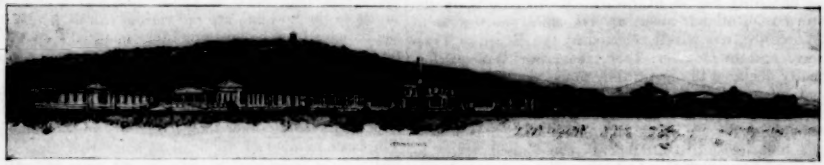
[1] Read before the Clinical Section of the Suffolk District Medical Society, November 15, 1899.

[2] This patient had so much improved that he had decided to leave and keep a hen farm. In the train he received a sharp blow on the chest, which was followed by a severe hemorrhage, from which he never rallied.

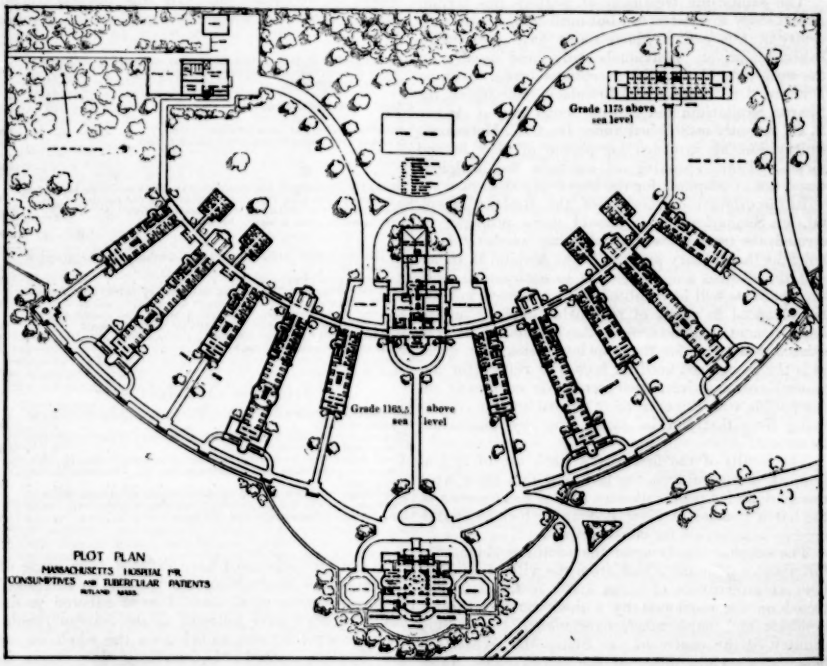
tion to health, even when there may be abnormal sounds in the chest remaining. The treacherous nature of the disease, however, has made me unwilling to use the term "cured" before many months have elapsed after cessation of active symptoms, even in cases where an apparent lack of definite signs would seem to make such a classification justifiable at the time of discharge. The term "much improved" is used in those cases in which marked amelioration of all or most of the prominent symptoms is noted, for example, cough, expectoration, temperature and weight, the degree of improvement of course varying in individual cases from a state of decided improvement to one almost reaching an arrest of disease, but where patients have been obliged for various reasons to leave the hospital contrary to advice. The term "improved" is used in those cases where only a slight degree or possibly rather marked improvement of the symptoms is noted.

CONDITION UPON ENTRANCE OF CASES DISCHARGED AS "ARRESTED."

Incipient cases with slight signs in one or both apices	27
Cases with signs somewhat advanced in one or both lungs	8
	35
Average stay in the hospital of the "arrested" cases (Maximum stay 10 months, minimum stay 6 weeks.)	4½ mos.
Average stay in the hospital of the total number discharged before October 1, 1899, and whose cases are considered in the report (115)	4 mos.
Average stay in the hospital of those "much improved"	4 mos.
Average gain in weight of the 35 arrested cases	15 3-5 lbs.
The largest gain in weight by any one of these arrested cases was	45 lbs.
The length of stay at the hospital of this patient was	6 mos.



PERSPECTIVE



Incidentally it may be mentioned that this case gave a history of cough for over six months previous to entrance, great loss of flesh and strength, with signs of disease in the tops of both lungs (dulness and moist

râles), and that all outward symptoms disappeared at least two months before discharge and she has remained in the same condition ever since.

The percentage of "arrested" cases of pulmonary disease is	30.97+
The percentage of cases "much improved" and "improved," together	46.10+
The percentage "not improved"	21.23+
The percentage of cases discharged "well," one of bronchitis only	.85
The percentage of cases who died in the hospital (one) .	.85

These facts are the result of careful examination of the patient, both as to the physical signs in the chest and the general condition at time of entrance and before discharge. It is a curious and interesting point that the percentage of arrested cases is almost exactly the same as that noted at the Sharon Sanitarium during the past eight years and is in accordance with the experience of others in sanitaria elsewhere. That this has been accomplished even when hampered by the lack of sufficient appropriation this year is additional proof of the efficacy of hygienic treatment alone in this class of cases. With larger means at our command we believe that even better results can be shown in the future.

In offering this paper for your consideration it should be distinctly understood that no claim is made thus far other than that the disease has been *arrested in its progress;* in other words, that cough, expectoration and fever have ceased; and that the general condition is one of apparent health, even though in some cases abnormal sounds have persisted in the chest. The crucial test of the efficacy of any method of treatment lies in its lasting effect. The subsequent histories, therefore, of these patients a few years hence will be of special interest and of even greater value than the present records.

In a paper before the American Climatological Association in New York last May I gave the subsequent histories of 34 arrested cases treated at the Sharon Sanitarium. The percentage of those who had remained apparently well after intervals varying from two to seven years since their discharge was gratifyingly large. The results moreover were instructive, inasmuch as in those cases where symptoms of the disease had returned it was, except in one case who died after an operation, either because of the apparently advanced condition of the disease at time of entrance, or in consequence of the patients' returning to unhygienic surroundings and occupations.

At Sharon and at Rutland constant effort is made to induce patients to seek some other form of livelihood than that in which the trouble arose, experience having taught us the necessity of this advice. Persistent effort in this direction will often accomplish much even in cases whose outlook for a change in their life work is far from encouraging at first.

One serious obstacle to success in some cases is the lack of funds to enable patients to remain a sufficient time under hospital supervision. Several discharged as "much improved" during the year were apparently on the highroad to renewed health and vigor but were obliged to leave Rutland from lack of means. This could and doubtless will be obviated in the future by a more generous appropriation, a part of which can be devoted to the support of such people during the necessary stay at the hospital.

METHODS OF TREATMENT AT RUTLAND.

Whatever good results have been obtained are due chiefly to hygienic measures alone. In following these methods much the same course is pursued as in other modern sanitaria for consumptives. Constant life in the open air, whether resting or exercising, is insisted upon. Except at the hours of rising and going to bed (at which times in winter the heat is turned into the wards), the windows are left open, varying somewhat according to the outside temperature, during the twenty-four hours. Sponge or plunge baths at regular intervals are an essential part of the treatment, while three hearty meals a day, with lunches of milk, eggs or their equivalent, are given. Pulmonary gymnastics are also taught and regularly practised. Little weight has been given to medicinal treatment except as an occasional adjunct to the other and more important kinds. One attempt has been made with a certain form of serum in a limited number of cases, but as the results were quite negative it was discontinued after giving it a fair trial. No record of the results should be given without expressing my sincere appreciation of the cordial co-operation of Dr. Marcley, the superintendent, Miss Thrasher, the matron, and the nurses, without whose aid, often under difficult conditions, little could have been accomplished.

To the indefatigable work of my assistant, Dr. Henry B. Dunham, we owe much of whatever success has been attained, and to his colleague, Dr. David P. Butler, Jr., my sincere thanks are due for his efficient help during the recent unfortunate illness of Dr. Dunham.

In thus showing you what is being done by our State for the treatment of tubercular disease, especially in its pulmonary form, I have endeavored as far as possible to avoid the much dreaded and much quoted "personal equation" in giving results which have been corroborated by others. That the sanitarium treatment of phthisis is *par excellence* the most efficacious method of checking the disease, I am perfectly convinced after a personal experience of eight or nine years. The fancied objections which not many years ago occasionally were, and even now are, offered against it, such as the depressing effect of the patients upon each other, the danger of infection upon segregation of consumptives, etc., are mere shadows of the imagination to those who have had any experience in the matter. The manifold advantages far outweigh any possible objections, and the results are far more gratifying than any attempt at less radical measures.

At the opening of the Rutland Hospital I confess now to having had considerable doubt as to the wisdom of building open wards, lest the lack of privacy would prevent many desirable patients from entering. All fear on this point, however, has long since been dispelled. The philosophy and good cheer shown by most, if not every one, of the patients, under present conditions, has been a most encouraging and inspiring feature of the place. The method of having open wards for a large number of patients has this distinct advantage, moreover, that it allows a much larger circulation of air and freer ventilation than would be possible by an arrangement of small cubicles massed together. The custom of single bedrooms, as in other much smaller institutions, is of course at Rutland impracticable on the ground of expense.

At other times and places I have spoken of the great need of such institutions not only in remote regions but in properly selected sites near our great cities. The fact that in three months after the first patient was received the hospital was filled to its

utmost capacity (about one hundred and seventy beds) corroborates this opinion; that similar institutions for incipient cases are needed in different parts of the State is also shown from the fact that the applications far exceed the capacity of the hospital, many of them being from western Massachusetts, the large majority, however, coming from the eastern portion, especially the vicinity of Boston. To increase the number of institutions moreover, rather than to greatly enlarge the capacity of the present hospital is much to be preferred. The largest sanitaria abroad with a corps of assistants have about 200 patients only. With a larger number we run serious danger of making the institution too bulky, and deterioration in the quality of work accomplished would almost inevitably follow.

Again I wish to emphasize what I believe to be one of the most important features of an institution of this nature; namely, its educational effect upon the community in general. Having positive proof of the beneficial effect of life in the fresh air, day and night, the patients preach this gospel far and wide to their families and friends with good results which I believe to be incalculable. Constant evidence of this is given in numerous letters received from former patients. During their stay they have had it impressed upon them that when they leave the institution they can act as missionaries, as it were, in the crusade against tuberculosis by teaching others the value of fresh air, proper diet, judicious exercise and cleanliness. That the lesson has not been lost upon them is one of the hopeful signs for the future.

To Massachusetts, then, belongs the credit of taking the first step in this direction in the United States. Indiana has lately followed her example, and if one may judge by the enthusiasm displayed at a recent meeting of the New York Academy of Medicine, New York will not be slow in following the example of her sister States. At that meeting a committee was formed to confer with the municipal and State authorities in consequence of a paper by Dr. Alfred Meyer, upon the Rutland Hospital. That many institutions of similar character will in another decade be established throughout the United States is more than probable.

One fact must, however, be recognized and guarded against. In the enthusiasm which marks the beginning of every new movement, we have to meet the inevitable errors of judgment and exaggerations of statement which, if not anticipated, will surely detract finally from the merits of any cause. Where popular interest is excited, as in this case, these dangers are more than doubled. Already we have been obliged to modify, if not deny, the exaggerated and often sensational statements of the lay press in regard to the Rutland Hospital. We, as physicians, are more or less prone to seize upon new ideas, and in the first glow of enthusiasm to paint with too glowing colors opinions which, under soberer judgment, have often to be modified, even when not completely abandoned. Progress seems to be always marked by the middle path between ultra-conservatism and blind enthusiasm.

In urging vigorous State action in the treatment of tuberculosis, we certainly cannot be accused justly of taking either extreme; we are simply building upon the idea which received its first strong impulse from Brehmer, in the mountains of Silesia, forty years ago; an idea which has steadily and surely grown, fostered by the patient and careful work of competent observers in Europe and America. Keeping in mind the fact that every method has its limitations and that as yet there is no known panacea, we can rejoice, nevertheless, in the public recognition of the necessity of using radical measures, as our State is now doing, believing them to be a great step forward, not only in the treatment but the prevention of tuberculosis. That the medical profession of Massachusetts, therefore, may strengthen by their personal influence the work just begun by the State is my earnest desire.

BRADYCARDIA, WITH REPORT OF A CASE.[1]

BY RICHARD F. CHASE, M.D., BOSTON,
Of the Medical Staff, Boston Dispensary; Instructor in Clinical Medicine, Tufts College Medical School.

BELIEVING that cases of persistent slow pulse are sufficiently rare and interesting to warrant reports, the following is submitted:

Mr. A., machinist, age seventy-five. His father and mother died of phthisis; four sisters and a brother died of heart disease; there is one brother now living, eighty years old. He has always used strong tea and coffee in liberal amounts, and for fifty years has consumed a ten-cent piece of tobacco daily, both smoking and chewing; of late this amount has lasted him a week. In alcoholic liquors he has indulged very moderately. There is no venereal history, and he has never received any injury of consequence. At the age of twenty-five he had rheumatic fever in several joints, of about three months' duration. From that time to seven years ago, he does not remember consulting a physician. Seven years ago he had an attack of bad breathing; said the doctor feared pneumonia, but was not confined to his room and fully recovered in a few days. At this time he gave up work and has done none since, although he has been well and active, frequently taking walks of several miles. For the past year he has been obliged to take occasional rests during the walks, on account of difficulty in breathing.

February 2, 1899, he consulted me on account of edema of both legs, scantiness of urine and general weakness, of about two weeks' duration. For past several months he has complained of a numbness of head, vertigo and faintness, but has never fainted; also of being short winded and always feeling cold.

Examination showed a man six feet in height, rather spare in flesh and active, of a calm nervous temperament. There was cyanosis of lips, nails and ears; the veins of hands and arms were very prominent; there was also some puffiness under the eyes and moderate edema of both legs and feet; no ascites. The pupils were contracted, but would react to light and accommodation. Knee-jerk and ankle clonus normal. The lungs and abdominal viscera were negative. There was no atheroma of radial, brachial or temporal arteries. Pulse in right radial while sitting was 30 per minute, strong, full and regular; the left radial the same, but less strong. A few minutes later while standing the pulse was 26 per minute.

Examination of heart. — Pulsation seen in epigastrium while sitting, not on standing. Percussion gave no enlargement; if any change, it seemed undersized. The apex beat was easily felt in the fifth interspace,

[1] Read in part before the Clinical Section of the Suffolk District Medical Society, November 15, 1899.

one inch within the nipple. At the apex the heart's sounds were heard, strong and labored; sometimes irregular, but usually regular; there was a soft, blowing, systolic murmur, transmitted to a little outside of the nipple and upwards for about two inches; not heard in the back. The pulmonic second sound was slightly accentuated. The sounds over other valvular areas were indistinct. The heart's systole and arterial pulsations were synchronous.

The appetite was fairly good, the bowels were regulated by a laxative. Acetate of potassium, 10 grains, three times daily, and tincture nux vomica, eight minims, three times daily, were prescribed. The patient at this time seemed very little inconvenienced by his affection.

February 22d. After ascending a flight of stairs the breathing was accelerated and the pulse was 32; after ten minutes, undergoing examination, pulse was 32; fifteen minutes later it was 30.

February 24th. Sitting, pulse 29. Edema diminished; less cyanosis; was passing more urine.

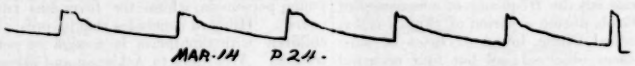
February 28th. Lying, pulse 29; twenty minutes later, 30. Edema still more dimininished; less trouble in breathing and feeling stronger.

March 2d. He was seen by Dr. Harold Williams at Boston Dispensary and shown to students. Immediately after going up two flights of stairs and being somewhat excited, the pulse was 34 and irregular.

March 5th. Edema nearly disappeared; no pitting. Pulse 24. Was seen by Dr. Twombly, who agreed in points of examination. During past several days had taken nux vomica irregularly.

March 10th. On account of the increased slowness of pulse, nux vomica was increased to 12 minims, three times daily, apparently without any effect. Examination of urine at this date was negative. Pulse 28.

March 14th. While taking a sphygmographic tracing, in which he was much interested, there was occasional irregularity of the pulse, which was 24.



March 17th. Pulse 27, standing; temperature 97°, respiration 26, following exercise.

March 19th. Pulse 27, standing; temperature 98°, respiration 21.

March 21st. Pulse 27, sitting; temperature 98°, respiration 20. Prescribed atropia, .01 grain, three times daily.

March 24th. Before going up two flights of stairs hurriedly, pulse 26, respiration 24. After, pulse 28, respiration 29. Some edema present; mouth very dry; pupils dilated. Omit atropia; take potassium acetate, 15 grains, three times daily.

March 30th. Pulse 29.

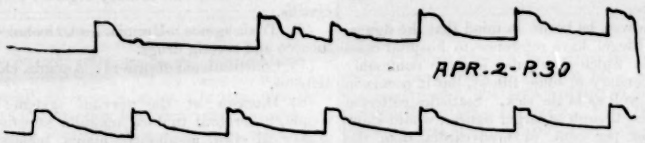
April 2d. Edema slightly diminished; slight pitting over tibiæ. Urine increased; gets up once at night, but has not formerly. On my arrival, pulse was 28, temperature 98.6°, respiration 22. While using the sphygmograph the pulse reached 36, the highest I had ever counted it. There was also an occasional irregularity, as noted on previous occasions, usually when patient was excited; the condition is shown by tracing of this date, the only time I succeeded in catching it with the sphygmograph. The high pulse rate and occasional irregularity I could not account for, as the patient was not excited; there was no apparent cause. This was the last time I saw him.

April 4th. He walked to his daughter's, a distance of three-quarters of a mile. On his arrival did not seem fatigued or out of breath; he sat down and talked a few minutes. Shortly his daughter, not receiving a reply to a question, looked up and saw that he was very pale and motionless — "looked as if he was dead." In a minute consciousness returned. He became purple, spoke a few words and vomited; afterwards he felt all right. Directly after a light dinner he had another attack; recovered in two minutes. He sat up that evening and talked as usual, retired at 8 P. M., slept well and arose next morning refreshed, but a little weak. During the morning of April 5th he had three attacks; could tell when they were coming on. That afternoon he went to bed, had one severe attack and died. A physician who was called said the pulse was as low as 25.

An autopsy could not be obtained.

The features of this case which seem of interest are, (1) the cause of the slow pulse; (2) the duration; (3) the influence of the excessive amounts of tea, coffee and especially tobacco; (4) the relation of the valvular lesion to the slow pulse; (5) the rise of pulse and temperature three days before the patient died.

It will be seen in the following list of cases that this case is assigned to a class in which the cause is rarely determined before death, and not always, by any means, at the autopsy. During his illness seven years ago, he said "the doctor took his pulse and remarked that he had some fever," and he inferred that the rate was high. From correspondence with the physician I found he did not remember the case; had there been a markedly slow pulse, it seems probable that he would have recalled it. The duration of the symptoms has been less than one year, and probably the slow pulse did not much precede them. Tea, coffee and tobacco



have been assigned as causes of bradycardia; that either was the cause in this case would be difficult to prove. Bradycardia, as we all know, is rarely met in valvular lesions, its presence from whatever cause might be expected to interfere with compensation, and in this case it seems not improbable that it may have done so. That the valvular lesion was the cause of the slow pulse there is no way of determining. In any similar case a spasmodically increased pulse rate without apparent cause would to me be an ominous sign.

Another case that recently came under my observation will serve as an example of another very different type of bradycardia, and may warrant a brief report.

Man, forty years old, health generally good. Examined him in May, 1899, with reference to his heart, which was found normal; pulse the same. Was called to him in October, 1899, on account of an attack of indigestion, and found the pulse 43 and 45 per minute. During the hour I was with him it did not exceed 45, and was synchronous with the heart's systole. The next morning the patient was feeling quite well and the pulse was 90; three days later it was 74 per minute. There were no symptoms referable to the slow heart's action; the duration probably did not exceed twenty-four to forty-eight hours. The cause was most probably a reflex one arising from the stomach.

The term "bradycardia" has been given by Grob to those cases of slow pulse which are synchronous with the heart's systole, the rate being less than 60 per minute. The term has, however, been incorrectly applied to cases in which the pulse and heart's systole were not synchronous, the pulse for some reason failing to indicate every ventricular contraction. Moreover, there has been a tendency with some writers to accept only a lower rate, as 50 or under, as constituting a bradycardia. Hence there is confusion not only regarding the rate but the frequency of occurrence of bradycardia. Grob, during a period of three years at the Zurich Medical Clinic, found 82 cases of slow pulse in 3,578 cases observed; all but four occurred in males. Riegel, in seven years' observation at the Giessen Medical Clinic, found 1,041 cases in 7,567 patients; 710 were in males, 331 in females. On the other hand, R. Gossett Brown in 1889 said: "In many thousands of cases both in hospital and in private practice, I have twice seen cases of slow pulse." The most obvious reason for this discrepancy in observations would seem to be a difference in pulse rate referred to, that of Brown's probably being much lower than that given by Grob. Accepting Grob's rate, cases of bradycardia may be considered of fairly common occurrence.

It must, however, be borne in mind that the figures of Grob and Riegel have reference to hospital cases only, a class in which slow pulse is more commonly met, being secondary to some illness, but it occurs in the healthy as well as in the sick. Statistics collected from all sources, though of larger figures, would show a much smaller per cent. of bradycardia than the above. Prentiss, who in 1889 must have made a diligent search for individually reported cases, collected 94. To this number I have been able to add but nine cases reported since 1889, making a total of 103 cases. This collection differs from that of Grob's and Riegel's in embracing a far larger proportion of the unusual types. Of these 103 cases, excluding those due to fatal injury and others in which the age is not given, we have 77 cases, of which the average age is found to be fifty-three years. Adding 84 of these cases in which the sex is recorded to Grob's and Riegel's collections we have a total of 1,207 cases, which is a larger number and offers a greater representation of all classes than any statistics previously presented. Of these 1,207 cases we find over 70 per cent. occurred in males. The fact that bradycardia is more common in males than in females has given occasion to Morison for an article on this feature, in which he concludes: "The belief is justfiable in the meantime until statistics prove the contrary that the constitution of the male more frequently results in bradycardia than do the like conditions in the female, although large statistics show that heart disease is more common in women than in men."

The conditions in which bradycardia occurs are of interest, and are well given by Riegel in his classification, which, by the way, is the one most generally accepted. It is as follows:

(1) Physiological bradycardia.

(2) Pathological bradycardia.

Physiological bradycardia includes those cases due to physiological conditions only. Probably Napoleon's case is the best-known example of this type. The condition is reported to have been observed in entire families. It occurs in the puerperal state at full term, abortions and premature labors; also in fasting and other conditions. In any case of slow pulse an extended observation may be necessary to determine its class.

Pathological bradycardia embraces all cases not physiological. It occurs in the following conditions:

(1) Convalescence from acute fevers, such as pneumonia, typhoid fever, erysipelas, scarlatina, diphtheria, acute rheumatism, and the like. It is most seen in young persons in whom the fever has run a normal course. Hibbard concludes that its presence in young children with diphtheria is a sign of serious heart trouble. According to Atkinson and others, it is met with in the beginning of acute rheumatism as well as in convalescence.

(2) Diseases of the digestive system: Acute, chronic and nervous dyspepsia, ulcer and cancer of stomach, and esophageal affections.

(3) Respiratory diseases: Emphysema, bronchitis, pleuritis and laryngeal affections.

(4) Circulatory disturbances: Myocarditis, fatty degeneration of heart, pericarditis and arteriosclerosis; not common in valvular diseases.

(5) Diseases of the urinary organs: Nephritis and cystitis.

(6) Toxic agents: Uremia, lead, alcohol, tea, coffee, tobacco and certain drugs.

(7) Constitutional disorders: Anemia, chlorosis and diabetes.

(8) Diseases of the nervous system: Epilepsy, apoplexy, cerebral tumors, medulla affections, injury to cervical cord, meningitis, mania, melancholia, and the like.

(9) Various other affections, as skin diseases, affections of the sexual organs, sunstroke, etc.

After giving these divisions and subdivisions, Riegel feels that there are still cases which may not properly

come under this grouping, and mentions as an example those cases in old persons in whom some affection of the heart or blood-vessels, most probably due to old age, is the cause of the slow pulse. Again, of the 94 cases by Prentiss, in 35 no cause is assigned for the slow pulse. This is of particular significance for the reason that every writer has probably done his utmost to ascertain the cause.

For the above reasons, but more particularly from the observation of one of these cases and the study of many reported cases, I am led to believe there is a class of case which thus far has not received its due amount of consideration. In confirmation of this belief I present a series of cases which, both in number and in similarity to one another, seem sufficient to establish a class of their own. In number they constitute about one-third of all the individually reported cases, and undoubtedly many more might be added to this list; were they not of particular interest they probably would not have been reported.

Of 33 cases in which the age is given, the average is found to be over sixty years, and but one case occurred under forty years. Of 34 cases in which the sex is recorded, 30 were in males. In more than half of the cases the duration has been years; in any case it was probably longer than was recorded, as the condition is rarely discovered in the very beginning. The pulse rate recorded was the lowest observed, and although it may not have remained at that point it usually continued low to the end. From the fact that in these cases the slow pulse was persistent, whereas in other cases of a different type it is a temporary condition, Truffet has divided all cases into (1) *Transitory* and (2) *Permanent* bradycardia. This division, like all others, has been more or less criticised. The temperature in the few cases recorded was subnormal, except perhaps near the end.

The bradycardial symptoms referred to consist of attacks of syncope, vertigo, dyspnea and sensitiveness to cold, all of which may be due to disturbances of the circulation, resulting from the slow pulse. These symptoms were present in all but one case. It is of interest to note that in a large number of these cases no accompanying disease has been apparent, and even in those cases attended by some affection it would often seem a question of how much influence it may have had on the bradycardia. From the indiscriminate use of the terms "epileptic," "epileptiform" and "apoplectic" in the reports of these cases, it is difficult at times to determine if a true epilepsy or apoplexy were present. Perhaps attacks of syncope may have been mistaken for true "epileptic fits."

BRIEF REPORTS OF THIRTY-FIVE CASES OF SLOW PULSE, DESIGNATED BY THE AUTHOR AS CASES OF IDIOPATHIC BRADYCARDIA.

No.	Sex.	Age.	Duration.	Bradycardial Symptoms.	Lowest Pulse.	Temperature.	Respiration.	Accompanying Disease.	Termination.	Autopsy.
1	M.	54	Years.	Present.	12+	94.5-98°		None mentioned.	Died in attack.	Thorough but negative.
2	M.	63	"	"	36	96°	20	" "	Living.	
3	F.	75	"	"	34			" "	Living.

Author's.	"	75	Weeks.	"	24	97°	20	Valvular.	Died with attacks.	

Numbered cases are taken from Prentiss's collection.

In the cases where a fatal termination has been reported, many times it seems to have been caused by the bradycardia, the person dying in, or directly following, the attacks of syncope. Fatty degeneration of the heart and atheroma were most frequently found in the ten autopsies; in some, however, there were no pathological conditions which might be assigned as the cause of the slow pulse. This is the type of case we see reported under the headings, "A remarkable case of slow pulse," "An unusual case of persistent slow

pulse," and the like. Unlike the cases due to acute fevers, digestive disturbances, etc., this type is rare; from the usual fatal termination it becomes of especial interest and warrants consideration. Should it not then be assigned to a class of its own? Two classifications have already been referred to, Riegel's and Truffet's.

Riegel's classification is based on the physiological and pathological conditions supposed to exist, for certainly our knowledge of the physiology and pathology of bradycardia at the present time warrants but little more than a supposition in any case. Besides, under one heading he groups those temporary cases usually terminating favorably, together with the persistent cases generally ending fatally. Surely a distinction should be made between these two classes.

Truffet, as I have said, bases his classification on the duration, and places under one division those persistent cases generally believed to be due to physiological conditions, and not affecting the health, together with the persistent cases ending fatally. Here again a distinction should be made, if possible.

Flint has divided all cases into "functional" and "organic." But this division, like Riegel's, calls for a knowledge of the pathological conditions, which we lack.

Without entering further into a discussion of this feature, let us understand (and it is hoped it has been made clear) that there are three types of bradycardia, which differ from one another either in cause, duration, symptoms, or termination. Then let us assign each type to a class of its own. Such a division, one consisting of three classes, has been made by Grob, and he has used the terms "physiologic," "idiopathic" and "symptomatic," which are perhaps as significant as any, and to avoid the introduction of new terms it seems best to use these, but with a somewhat different assignment of cases. Thus we have (1) *Physiological* bradycardia, (2) *Idiopathic* bradycardia, (3) *Symptomatic* bradycardia.

Physiological bradycardia includes those cases due to physiological conditions only. This class is fairly well agreed to by all writers on the subject.

Idiopathic bradycardia may embrace those cases of persistent slow pulse usually occurring in advanced life and more commonly in the male sex, accompanied by the usual bradycardial symptoms, but rarely attended by any discoverable disease which is the cause; the termination is usually fatal, though cases have been known to last for years without seriously affecting the health.

Symptomatic bradycardia should include all cases embraced by Riegel's pathological division, excepting the above classes. To this class belong those cases in which the pulse is symptomatic of some usually apparent condition, ordinarily of temporary duration, but it may include cases terminating fatally from injury, sunstroke, poisoning and certain other serious conditions. As has been said, all classifications are subject to criticisms, but it is hoped the one now offered may in a degree serve its intended purpose.

Cause. — The immediate cause of bradycardia may be due to (*a*) a condition of the nerve centres producing either irritation of the pneumogastric or paralysis of the sympathetic (accelerator) nerves of the heart; (*b*) a condition of the pneumogastric increasing its irritability; (*c*) a condition of the sympathetic nerves paralyzing them; (*d*) or to some condition of the cardiac ganglia in which the influence of the pneumogastric preponderates; (*e*) or a condition of the heart muscle whereby it fails to respond to the normal stimulus; (*f*) or to poisons acting either on the nerve centres or endings.

Pathology. — Our knowledge of the physiology of bradycardia is limited, and the same is true of the pathology; at the same time, regarding the pathological causes of bradycardia we are not lacking in theories. The following 31 autopsy reports give some idea of the pathological conditions thus far observed.

Disease of Brain. — Hydrocephalus, Cases IV, XXIV and XLV; softening, Case XXXIX; adhesions, Case XXV; abscess of medulla, Case XXVIII. Total, six cases.
Disease or Injury of Cord. — Fracture of cervical portion, Cases XXIX, XXX, XXXI, XXXII, XXXIII, XXXIV, XXXVII; induration, Case XXXV. Total, eight cases.
Disease of Heart. — Fatty degeneration, Mayer's, Cases XXXVIII, XVIII; ossification of aortic valves, Case X; hypertrophy, Case XXII; dilated, Case XIII; heart flabby and mitral lesion, Case I.; mitral lesion, Case LXXVIII; aneurism of ventricular septum, Case XLVII; gumma of ventricular wall, Coggeshall's. Total, ten cases.
Disease of Circulatory System. — Ossification of coronaries, Claybaugh's, Case XXI; arteriosclerosis, Hanot's, two cases; ossification of aorta, Case VIII. Total, five cases.
Negative. — Cases I, LXXXVI. Total, two cases.
Numbered cases are taken from Prentiss's collection.

Prognosis. — From what has already been said it is believed the prognosis of the various types of bradycardia is fairly evident.

Treatment. — As to treatment it is also evident that many cases require none, the removal of the cause effecting a cure. In those cases where the patient suffers from the result of a slow pulse, and in which life may be threatened, rest and certain drugs seem indicated. Strychnia, atropia and nitroglycerin are most commonly used, but in the majority of cases without any beneficial effect.

A complete review of this subject has not been attempted. If the reader's attention has been directed to the following points the object of this paper is attained.

(1) A pulse rate under 60, which is synchronous with the heart's systole, constitutes a bradycardia, accordto Grob.

(2) The condition, all classes considered, is of common occurrence.

(3) It is much more common in males than in females.

(4) There are three types of bradycardia, as classified according to their clinical aspects.

(5) The class here termed idiopathic bradycardia, on account of its usual fatal termination, must not in any case be passed by as a mere curiosity.

A BRIEF NOTE ON SOME OF THOSE GRAVE ABDOMINAL LESIONS WHICH OFTEN DEFY DIAGNOSIS.

BY THOMAS H. MANLEY, M.D., NEW YORK,
Visiting Surgeon to Harlem Hospital; Professor of Surgery, New York School of Clinical Medicine.

IT is a fundamental principle in our profession and in the science of the healing art, that the first step in the management of a case is to study, interpret, and elucidate symptoms and signs; in other words, make a diagnosis. And, generally speaking, the art of diagnosis has of late years spread far in advance of the power to arrest or cure disease.

Abdominal lesions, traumatic or pathologic. — The above holds good in the lesions of any organ in the body; however, there yet remain very many pathologic conditions within the abdominal cavity wherein definite diagnosis is not possible, except through the breach made by the surgeon's scalpel, the exploratory incision, and exploratory manipulation, something which under many circumstances greatly adds to the gravity of many cases.

Hemorrhage, perforation, obstruction, or enteric paresis. — Very often, after a grave abdominal contusion, who can say with certainty which one of the above conditions prevails? The patient is in shock, with a distended belly; in pain; is vomiting, and depressed in spirits. He is anxious to live and ready to take the chances of an operation. But let it not be forgotten that injudicious operations kill. Our responsibility here is terrible when we properly view the case, and assume for the moment that the patient is a member of our own family.

Without operation. — But we endeavor to quiet our conscience by affirming that the patient "must die in any event." This is a vicious conclusion, as we all know that the abdominal viscera possess remarkable power of safely adjusting themselves to many pathologic conditions. Intra-abdominal hemorrhage is rarely mortal *per se*. Stimson, some years ago, showed by statistics that of the penetrating gunshot wounds of the abdomen, the mortality was larger after laparotomy than those cases treated on conservative lines. Reclus, of Paris, has demonstrated the same condition of affairs. The latest surgical reports from the campaign in South Africa by Sir William MacCormac[1] point strongly in the same direction.

The late Hispano-American imbroglio again showed that there was no place for "abdominal surgery on the battlefield," as the few who had the abdomen opened for bullet wounds succumbed, while all those who were left alone did well.

If in doubt, don't interfere. — Unless our patient is in fairly good form, or unless the symptoms point unequivocally to the seat of a lesion which *we know* to be definite, leave the patient alone, or rather follow closely on conservative lines. Unhappily, in our days, there is altogether too much surgery of the abdomen done simply for the purpose of "operating."

When death follows an acute abdominal lesion, before reacting inflammation sets in, it is invariably attributed to *hemorrhage* or *shock*. The rupture of a hollow viscus is always followed by great shock. To operate on one in this state deprives him of his only hope of recovery. Rather wait till reaction sets in, though we have then to deal with peritonitis. But let us not open our eyes in amazement at the mention of "peritonitis," for this follows every so-called "aseptic" operation performed in the peritoneal cavity, even when very good recoveries are secured. The French use the refined term "*peritonisme*" for this post-operative condition.

Perforation or mechanical obstruction. — Will not some of those of a fervid imagination and who have an explanation for everything be kind enough to point out the fundamental distinction between the symptoms of perforation and those of obstruction? Absence of hepatic dulness is a fairly certain guide in some instances, but it may be wanting. In both the onset is sudden; the patient is seized with furious colic, just such as is noticed in acute hepatic, renal, or appendicular stenosis. Manipulation of the abdomen, with the history of the case, will not always assist us in ferreting out the seat of trouble.

But, with some grave cases, there is no antecedent history of any moment; the abdomen may be clothed by a six-inch layer of abdominal fat, or it may be as hard as a plank from muscular spasm.

Traumatic and pathologic conditions. — In traumatic conditions leading us to suspect grave intra-abdominal lesion, the time to operate, if to operate at all, is indeed a serious problem; but in pathologic states, with but few exceptions, indubitable signs or symptoms of perforation or obstruction call for prompt surgical interference as the only means of saving life.

Crushes of the abdomen with grave symptoms. — When laparotomy is performed after violent compressive or concussive force has been sustained the mortality is very great.

To do a laparotomy for a moderate intraperitoneal hemorrhage is an inexcusable blunder, as it places life in needless jeopardy for a condition comparatively harmless in itself. When the extent of visceral disorganization is large, with few exceptions, the only effect of a laparotomy is to shorten life. In violent abdominal contusions after evisceration, we are frequently unable to immediately determine just what extent of gangrene may later follow.

In this class we should hesitate, deliberate, and weigh our cases well before we commit them to the last extremity of major surgery. I can recall about a dozen such cases in my own practice. Not a single one survived that was laparotomized. As the full course of anesthesia was approached their eyes closed, never to open again, for but few of them ever rallied from the shock. Three of such cases have come under my care within a year.

CASE I. A vigorous young man riding a "wheel" collided with a heavy watering-cart, was thrown down, both wheels passing over his body, just above the umbilicus. Brought to the hospital in desperate shock. Six hours later, rallied somewhat. Belly ballooned, hypersensitive, lower extremities drawn up, vomiting, but no blood, hands cold, pulse thready, bedewed in a cold perspiration, suffered agonizing pain till morphine was freely given. Hepatic dulness absent, abdomen tympanitic to percussion, rather of the character of *false* meteorism than true or *enteric*.

Operation. — Everything in readiness for complications or accident, etherization was begun and continued

[1] Lancet, January 20th.

with caution. A central incision through the median *raphe* above the navel was made, the peritoneum punctured, when there issued through, first a gush of gas, then fluid blood and clots, with semi-digested food and fecal matter. There had not been very much blood lost. The transverse colon was torn off from the gastrocolic omentum, the bowel laid open on its anterior border. Drawing the stomach out through the incision, a rent completely through its posterior wall near the cardia was found. Liver was not injured; blood oozed up behind the hepatic flexure of the colon. Exploring deeply, came on a rent in the capsule of the right kidney; this was sutured and bleeding arrested. Wound in colon closed easily and quickly, the one in the posterior wall of stomach reached and sutured with great difficulty. The small intestine was then completely turned out, when it and all the viscera were scrutinized. Peritoneal cavity was well washed and dried. Abdominal incision closed. Returned to bed in great collapse. Reacted well. At midnight had report that his condition was excellent. Called at 6 A. M. at hospital myself, to find that he suddenly sank at 3 A. M.

Autopsy at 5 P. M. same day. Rents sutured had closed completely, there had been no consecutive hemorrhage. Such had been the melancholy end of a case wherein recovery had been hoped for.

CASE II. Patient, a young man twenty-seven years old, was working a large circular saw, when he was struck sideways by a large splinter of plank. His left forearm, which was flexed at the time he was struck, was fractured through both bones. Timber glanced and hit him in the hypogastrium, knocking him down. Saw him three hours after the accident. In deep shock and great agony. Was prepared for laparotomy. On opening the abdomen there issued forth an enormous gush of bright red blood. There was found a deep laceration in the left lobe of liver with evident rupture of the celiac axis. Notwithstanding large intravenous injections of saline were given mortal symptoms so rapidly culminated that we had to discontinue intra-abdominal manipulations and close the incision, but before it was completed the patient was dead. An autopsy was not permitted.

This was a case in which there was no evidence of perforation of any of the hollow organs, one in which it seemed to me that full stimulation and free opiates might have afforded the patient a chance.

My experience has been that the value of intravenous injections has been much overestimated. They certainly, alone, are not to be trusted in acute traumatic anemia. I am inclined to believe that by rapidly diluting the blood, impairing its hemostatic properties, and by distending the arterial system, this excess of aqueous material very much interfere with nature's provision against death from hemorrhage.

CASE III. A boy of twelve years fell from a cherry tree, striking his abdomen on the rail of a fence. Was brought into the hospital in great distress. Had free vomiting, tympanitic abdomen, absence of hepatic dulness. Nine hours after entrance, *sectio abdominalis*. Large escape of gas and blood intermixed with chylous elements. A rent in the anterior wall of the stomach and through the jejunum in upper fifth were found. There was free bleeding from the mesenteric vessels, which were ligated and rents quickly closed, but before peritoneal toilet was completed, patient succumbed. Autopsy denied.

Might this last case not have survived by symptomatic treatment alone? With the rents in the alimentary canal and chylous leakage, it might seem preposterous to make such an inquiry, but facts are hard things to get over. The peritoneum, we know, possesses remarkable digestive and absorbent properties. An intestine heals with astonishing rapidity, and the jejunum being generally empty there is little chylous material to escape.

My sad experience with these three cases, coming rapidly after each other in one year, chilled my enthusiasm for early operation in this class. Unless we are assured beyond all doubt that a large rent or rupture of a hollow organ is involved, immediate section for violent contusions of the abdomen should be discouraged, and under any circumstances before reaction is established it is a desperate resource of very questionable expediency.

Clinical Department.

A CASE OF MULTIPLE CEREBRAL HEMORRHAGES FROM CHRONIC LEAD POISONING, WITH NECROPSY.[1]

BY J. W. COURTNEY, M.D., BOSTON,
Assistant in Nervous Department, Boston City Hospital; Visiting Physician to the Home for Incurables, Dorchester.

THE reason for the vague title first given to this communication lies in the fact that when Dr. Ogden spoke to me about it, a week or more ago, the brain which I have to show had not yet been sectioned.

The clinical history of the case is as follows: The patient, a married man of forty-one and a painter by occupation, presented himself for treatment at the Nervous Out-Patient Department of the City Hospital on the 18th of September last, complaining of constant headache, dizziness, muscular tremor, and, at times, nausea. The headache was vertical and occipital, and extended down the back of the neck, especially on the right. There was some complaint of deafness for the past year. The patient was said to be excitable and irritable and to be suffering from some impairment of memory. His family history was negative from a nervous and mental standpoint. As to his personal history, he said that he had always been well except for two attacks of colic, the first of which occurred six years ago and lasted for about five weeks; the second was in June, 1899, and was slight in character, but accompanied by dizziness, nausea and vomiting. Consciousness was lost on one occasion during this attack, and altogether the patient was confined to his bed for about ten days. From this time he claimed to have never fully recovered, and he had done no work for over a year on account of general weakness. Venereal disease was strongly denied, as well as excess in alcohol and tobacco.

The physical examination made September 18th reads: "Slight tenderness of right occipital region and superior curved line, down the neck and right posterior lateral region. No tenderness over mastoid. Station good. Pupils react to light and accommodation; external ocular muscles normal. Tongue protruded slightly to right; blue line on gums. Heart

[1] Read before the Clinical Section of the Suffolk District Medical Society, November 15, 1899.

negative, except that second sound is accentuated over whole cardiac area. There is a moderate tremor of hands, which is increased during excitement. Knee-jerks good; no clonus. No tenderness about legs."

The urine showed specific gravity 1.012; albumin one-tenth per cent.; no sugar.

A diagnosis of lead poisoning was made, the patient given KI, 10 grains, three times daily, and referred to the Ear Department for examination.

A note by Dr. J. J. Thomas a week later reads: "Temperature 99°; headache pretty constant; no epistaxis; bowels regular."

Dr. E. M. Holmes, of the Ear Department, reported: "The cerumen in this man's ears could cause his vertigo and tinnitus. There is a chronic dry middle-ear inflammation and some tension on membrane. This can be relieved."

A further note by Dr. Thomas, under same date as above, says: "Abdomen negative, no rose spots; spleen not palpable."

The iodide was continued and sodium phosphate in 10-grain doses was given to aid elimination from the bowels. A specimen of urine was sent to Dr. Ogden for lead examination.

I first saw the patient on October 2d. His main complaint then was of excruciating pain in the head, with occasional nausea and vomiting. The pain was located by him chiefly in the left side of the head and the vertex, and somewhat in the left frontal region. He had also noticed that his vision was failing. There was marked pallor of the face and mucous membranes, but except for the tremor, which was flexor-extensor in the hands and involved also the face, physical exploration was negative.

On account of the exceptionally intense character of the headache, associated as it was with nausea and more or less vomiting, I was impelled to believe that lead was not the only factor present in the case, and entertained the possibility of cerebral neoplasm. With this idea in mind I referred the man to the oculist, for examination of his eye grounds, and on October 11th received the following report: "This patient is hypermetropic and is wearing suitable glasses. The media and fundi are clear, but the right optic disc is moderately hazy, the left much less so. While the condition may be normal for him, I think it would be well to see if it changes any."

October 23d, Dr. Ogden reports: "Trace of lead in 500 cubic centimetres of urine."

The patient says that he has been in bed for a week past on account of the pain in his head. This pain has been so intense as to make him shriek and groan, and for three nights in succession gave him no sleep at all. While talking to me he complained of pain in the vertex, as if some one were pulling his hair out by the roots, and said that slight shaking of the head or movement of the jaws was sufficient to start the pain. He had had no diplopia.

A second examination of the eyes was made on this day by Dr. G. H. Thomas, and the following noted: "The outline of the right disc is slightly more hazy and that of the left decidedly more hazy than at last examination. To my mind there is a distinct swelling of both discs."

In my subsequent handling of the case I was led by the following considerations: Here was a man who had not been exposed to lead for about a year; who had had no colic for many months; and who presented none of the peripheral nerve lesions common to lead poisoning. Furthermore, examination of his urine for lead had shown only a slight trace in 500 cubic centimetres. For these reasons, and from the fact of the great rarity of cephalic manifestations of lead in this community, I was inclined to view lead merely as a contributing element, and favored the idea of cerebral neoplasm. This idea was strengthened, as I have hinted, by the persistent and constantly increasing headache, by the nausea and the beginning papillitis in both eyes. The tremor I considered might be consistent with either lead or tumor. As to the nature and seat of the new growth, I naturally did not attempt to form a positive idea from the data at hand, but with the intention of excluding gumma, I applied the therapeutic test of mercury. This soon produced a stomatitis and was stopped.

On the 30th of October, twenty-eight days after I saw the patient for the first time, and about a month and a half after his first advent to the hospital, he reported that his headache was still constant but not so severe. He went home, passed a fairly good night and in the morning his wife went off as usual to her work, leaving him comfortably fixed in bed. At noon one of the neighbors came in to get him something to eat and found him dead.

Through the family physician, Dr. R. J. McCormack, of Roxbury, I was enabled to obtain a necropsy, and this was kindly done for me by Dr. Joseph Pratt, of the Pathological Department of the City Hospital, some four or five hours after death. The head only was opened. The calvarium was normal, but the dura was much injected and seemed to adhere over the left frontal region. There was much serous dripping from the brain and the convolutions generally showed abnormal flattening. Palpation of the brain was practised but yielded no results, so it was decided to harden it *in toto* in formalin without further examination.

Two days ago, Dr. Pratt made anteroposterior vertical sections of the brain for me, with the results I am about to show. As we proceed from front to back in this series of sections we find, first, in the right hemisphere, what is evidently a recent small hemorrhage occupying the gray matter of the upper portion of the ascending parietal gyrus, and another, and smaller, in the first temporal gyrus. From this point until we reach the left crus cerebri nothing abnormal presents itself, but here you can see the beginning (or rather ending) of a hemorrhage which may be traced backward along its long axis longitudinally into the centre of the ventral part of the pons. This hemorrhage measures one and seven-tenths centimetres in length and is four-tenths centimetres in its average width. Near the periphery of the pons, also on the left side, you notice a second, though very minute, hemorrhage. The tissues surrounding both hemorrhages are blood-stained.

From the general convolutional flattening which was noticeable when the brain was in a fresh state, and from the findings just pointed out, we are naturally constrained to look upon lead as the sole causative factor in the case; its modus operandi having been to produce blood dyscrasia and renal irritation — the latter as evidenced by the albuminuria — and then the arterial breakdown which caused the fatal issue. Optic neuritis, as you all know, sometimes occurs during the course of chronic lead intoxication. As to the

headaches, I can only say that they were the severest I ever encountered unassociated with cerebral neoplasm. The absence, clinically, of those psychical manifestations which are grouped under the title of "encephalopathia saturnina" is interesting in view of the diffuse arterial disease which the widely-separated hemorrhages would lead us to suppose was present in the case.

In conclusion, I must say that the case, taken as a whole, seems to me a rather unusual and instructive one.

Medical Progress.

RECENT PROGRESS IN OBSTETRICS.

BY FRANK A. HIGGINS, M D., BOSTON.

MATERNAL IMPRESSIONS.

LEWIS,[1] in a review of the subject of maternal impressions, says that if maternal impressions explain human anomalies, they should also explain such occurrences among the lower animals and even among plants. Monstrosities are perhaps more common among domestic animals and fowls than among men. The strongest blow is dealt to the theory of maternal impressions by the results of experiments in the production of monsters artificially. Innumerable experiments have been performed upon the eggs of bird, fish, insect and echinoderm which have resulted in the production of almost all the typical varieties of monsters, especially of single monsters. Different varieties can even be produced at the will of the experimenters by different ways of managing the eggs. Monstrosities can be artificially produced in the embryos of birds exactly like those which, occurring in human fetuses, are ascribed to mental shock or nervous impression of the mother. It has often been observed that fish eggs hatched in running water produce a far greater number of double embryos than do those hatched in still pools. The shaking caused by railroad or wagon journeys to the hatchery also results in a greater profusion of double monsters. In human fetuses, even at full term, there are sometimes found remains of amniotic bands and adhesions which, obviously, by interfering with development of different parts at an early period of gestation, were the causes of various malformations. In short, all malformations and monstrosities can be explained by purely physical and mechanical causes, entirely remote from psychic influence, so that there is never any reason to invoke the mysterious or the supernatural to explain natural phenomena.

ANTISTREPTOCOCCIC SERUM IN PUERPERAL INFECTION.[2]

In 1898 the American Gynecological Society appointed a committee to report on the value of antistreptococcic serum in the treatment of puerperal infection. The committee reported at the 1899 meeting and their conclusions are quoted, and are interesting in that they help to strengthen what already was generally believed to be good judgment:

(1) A study of the literature shows that 352 cases of puerperal infection have been treated by many observers, with a mortality of 20.74 per cent.; where streptococci were positively demonstrated, the mortality was 33 per cent.

(2) Marmorek's claim that his antistreptococcic serum will cure streptococcic puerperal infection does not appear to be substantiated by the results thus far reported.

(3) Experimental work has cast grave doubts upon the efficiency of antistreptococcic serum in clinical work, by showing that a serum which is obtained from a given streptococcus may protect an animal from that organism, but may be absolutely inefficient against another streptococcus, and that the number of serums which may be prepared is limited only by the number of varieties of streptococci which may exist.

(4) Thus far the only definite result of Marmorek's work is the development of a method by which we can increase the virulence of certain streptococci to an almost inconceivable extent, so that one hundred-billionth of a cubic centimetre of a culture will kill a rabbit.

(5) The personal experience of your committee has shown that the mortality of streptococcus endometritis, if not interfered with, is something less than five per cent. and that such cases tend to recover if nature's work is not undone by too energetic local treatment.

(6) We unhesitatingly condemn curettage and total hysterectomy in streptococcus infections after full-term delivery, and attribute a large part of the excessive mortality in the literature to the former operation.

(7) In puerperal infections a portion of the uterine lochia should be removed by Döderlein's tube for bacteriological examination and an intra-uterine douche of four to five litres of sterile salt solution given just afterwards. If the infection be due to streptococci, the uterus should not be touched again, and the patient be given very large doses of strychnia and alcohol if necessary. If the infection be due to other organisms, repeated douchings and even currettage may be advisable.

(8) The experience of one of the members of the committee with antistreptococcus serum has shown that it has no deleterious effect upon the patient, and, therefore, may be tried if desired. But we find nothing in the clinical or experimental literature or in our own experience to indicate that its employment will materially improve the general results in the treatment of streptococcus puerperal infection.

FAT AND FECUNDITY.

Reed[3] says that the question, a natural one, as to which is the cause and which the effect in a given case of sterility, coexisting with obesity, is best answered by the history of the case, and the antecedent condition may generally be assumed to be the causal one. Thus in the case of a comparatively young woman who takes on fat and whose increase of weight is followed by a corresponding decline of sexuality, there is logical inference that the first condition is the cause of the latter. This assumption is confirmed when a reduction of the obesity is followed by a spontaneous return of the menstrual and reproductive functions. The physiological conditions underlying the normal deposit of fat are those of abundant supply of nutritive material, normal digestive functions, a free circulatory activity, an absence of excessive muscular exercise, a normal metabolism and the unobstructed elimination

[1] American Journal of Obstetrics, July, 1899.
[2] Loc. cit., September, 1899.
[3] American Medical Quarterly, June 1899.

of metabolic products. When, therefore, in a mature person, in whom the nutritive functions have attained a relative equilibrium, and in whom there occurs a change of type due to the sudden accession of fat, there occurs a re-establishment of the functions of growth, a disturbance in the balance between waste and supply, the latter preponderant. With this recurrence of growth there is also a readjustment of function approximating the prepuberty standard. There is progressive amenorrhea, genital anesthesia and loss of sexual desire, increasing to the clinical picture of a well-established case of sterility. The prognosis depends much upon the intelligent and persistent co-operation of the patient. The acquired obesity of this class may be cured practically always, while restoration of the genital function is less amenable to treatment. Plethoric cases are more easily cured than anemic, while the most tractable of all are those complicated with neurasthenia. The treatment of sterility due to obesity is both constitutional and local, varying according as the case may be anemic or plethoric, simple or complicated, and must embrace a consideration of diet, exercise, bathing, medication and general personal hygiene, while the local treatment must embrace all resources that are calculated to overcome manifest pathologic states and to re-establish the functional power of the genital organs. There is no special diet which should be employed in every case without more or less radical change, and any attempt to apply any one of the numerous so-called systems in a routine way is fraught with hazard.

THE CAUSES WHICH RENDER DIFFICULT THE LABOR OF CIVILIZED WOMEN.

Reid,[4] in a paper read before the British Medical Association, remarks that it is a well-founded belief that the obstetrical forceps is used much more frequently by men of the present generation than the past, and that the change was due, in part at least, to necessity, owing to the fact that there was a gradually increasing disproportion between the fetal head and the maternal pelvis. His belief was that the labors of civilized women were so severe that in the absence of skilled aid a very considerable proportion would perish, and even in cases where surgical aid was unnecessary delivery approached in severity a major operation, the effect of which a woman felt for a fortnight or a month. The labors of savage women were known to be safe and easy, and the question arose, how did civilization render labor difficult? Dr. Reid's view was that women with small pelves tended to have daughters with a like peculiarity, and people who at birth had large or small heads tended to transmit that peculiarity. When a savage woman had a small pelvis or a large-headed child, she generally died in labor. The race was thus purged, generation after generation, of all narrow hips and large heads, while the right proportion between head and pelvis was secured. In the highest civilization many small-hipped women and large-headed children were annually preserved. If these perished, the average difficulty of labor in the next generation would be artificially ameliorated. Here was the reason why the labors of civilized women were becoming increasingly difficult, and he thought that it was not improbable that about the end of the twentieth century forceps operations would be performed much more frequently than at present.

[4] British Medical Journal, August 26, 1899, p. 502.

SYMPHYSEOTOMY, FOLLOWED BY EASY FORCEPS TWO YEARS LATER.

Balfour [5] reports a case in which the patient at her first labor was delivered by craniotomy, at the second by symphyseotomy, after failure of forceps, and at the third labor, delivery was easily accomplished by forceps. The case is reported as of interest, because showing a permanent improvement in the size of the pelvis after the operation of symphyseotomy. The reporter comments on the case of the operation for symphyseotomy by the subcutaneous method, only a knife and a catheter being used, making it eminently suitable for small, dark and dirty houses where no skilled assistance can be had.

IS A SLOUGHING PROCESS AT THE CHILD'S NAVEL CONSISTENT WITH ASEPIS IN CHILDBED?

Dickinson,[6] under the above title, makes an elaborate review of the subject of umbilical cord ligation and sloughing and a plea for the application, in amputating the cord, of the surgical principles that govern other amputations. He says it is not a little curious that the earliest operation in the world, and the only one done on every individual, should be treated by measures that antedate our annals, namely, ligation and absorbent dressings. He lays down the following principles as being directly opposed to the prevailing practice:

(1) Mass ligature should be avoided. Hemorrhage follows the present method occasionally because shrinkage of the gelatine loosens the seizure. Ligatures belong on bared vessels.

(2) A hernial opening should not be closed by a granulation scar. Primary union is readily substituted.

(3) As in the funis the line of demarcation is known, removal should be practised at or beyond that point.

(4) That form of operation should be chosen which will do away with sloughing or pus production. Prevention of suppuration, of putrefaction in the stump and of systemic infection has been attempted by means of numerous devices and dressings. Removal alone is prevention. To frankly sever the cord at the skin margin with ligature of the vessels, or suture; one or both brings about safe, clean and prompt healing. Thereby, the navel of the second day looks like the navel of the tenth or fifteenth day under other methods.

The method used by him is to snip the cord with blunt-pointed scissors all around the skin margin. The sheath and gelatine are stripped backward with as much jelly as possible, leaving the vessels standing alone, and a fine silk or catgut ligature is put around. The vessels are cut off short and the stump tends to roll in. The stump may or may not be sutured. A dry gauze pad suffices for the dressing.

Objections to complete primary amputation: (1) Increased danger of contact infection, owing to operation on parts supplied with lymphatics, as compared with the ordinary ligation of vessels and jelly on parts having no nutrient capillaries or absorbents; (2) lack of drainage in case of infection; (3) danger of concealed secondary hemorrhage (hematoma) after the suturing method; (4) inaccessibility of vessel ends in case of bleeding as compared with facile placing of

[5] British Medical Journal, February 18, 1899.
[6] Transactions American Gynecological Society, 1899.

second ligature where stump is long; (5) the risk of striking an umbilical hernia; (6) as this is surgery it is not yet adapted to the general practitioner.

To admit most of these objections is to confess that we, as instructors and surgeons, fail in our attempts to drill the students in hand cleaning and instrument boiling, and avoidance of unclean contacts. The method requires hands no cleaner than for a vaginal examination and far less wound knowledge than for the repair of perineal injuries.

CÆSAREAN SECTION IN SEPTIC CASES.

It is beginning to seem quite possible that, owing to the increased knowledge of the technique of Cæsarean section, the comparative ease with which it is performed, and the low mortality rate, that operators may be led to resort to the operation in unsuitable cases, particularly those with possible septic infection, for which some other method of delivery would formerly have been found. We have considered that a dead child or a septic mother were almost positive contraindications to the Cæsarean operation, and if occurring with a pelvic tumor, the abdomen should be opened, the tumor removed and the child delivered by forceps or craniotomy. With this in mind, the case of Docktor[7] is of special interest, with his report of 21 cases collected in literature. The patient was a multipara admitted in labor, expulsion of the child being impossible because of a tumor growing from the sacrum. The necessity of Cæsarean section was positive; choice of method only remained. On extracting the child, which was dead, the appendages were found partly decomposed and the uterus contained offensive pus. Fortunately, through efficient help, the uterine contents were kept outside the abdomen. The womb was amputated, a strand of gauze was passed through the cervix for drainage and the upper borders of the stump united. The recovery from sepsis was tedious. She had a characteristic eruption, a pelvic exudate and pleuropneumonia, but recovered sufficiently to be removed to the medical department of the hospital, where her lung symptoms indicated a permanent tubercular infection.

Docktor's[8] studies of the 21 cases collected lead to these conclusions: The incision of the uterus, the extraction of its contents and suture of the womb was followed by a mortality of 40 per cent., while those patients that recovered had prolonged fever. A still worse result followed amputation of the uterus, with extraperitoneal treatment of the stump, the mortality of these being 40 and 50 per cent., and the patients who recovered suffered from pus formation in the stump and various septic complications. Those cases treated by amputation of the uterus, with intrapelvic treatment of the stump, did better than either of the foregoing, their mortality being 14.27, including the complications of sepsis, as in the other methods of treatment. So far as the comparison goes at this point, the best results are obtained by amputation of the uterus, with intraperitoneal treatment of the stump. The removal of the entire septic uterus and its contents, if possible, without contaminating the abdomen, would be the most desirable operation. This was effected in two cases by total extirpation of the pregnant uterus, through the abdomen, and in each case the mother recovered without complications. From these cases his conclusion is that in cases of septic infection, affording considerable risk in delivery through the vagina, the womb and contents should, if possible, be removed without being opened in the body of the mother.

THE ANTENATAL AND INTRANATAL FACTORS IN NEONATAL PATHOLOGY; AN ATTEMPT TO EXPLAIN THE PECULIARITIES OF THE MORBID STATES OF THE NEW-BORN.

Dr. J. W. Ballentyne,[9] of Edinburgh, presented a paper on this subject at the meeting of the American Medical Association at Columbus. The article is an able and interesting one, and the following is the summary of his conclusions: From all that has been said above it is clearly evident that if the characters of the diseases of the new-born infant are to be understood, it is essential that account be taken, not only of the facts that the infant's organism has just passed through a period of traumatism and is passing through one of readjustment to meet new requirements, but also that during the nine months of intrauterine life which precede birth, it may have been the sphere of morbid processes which have left their impress on it. It may come into the extra-uterine environment already diseased and malformed, or predisposed to some pathologic development. Like pregnancy, neonatal life is an epoch which has a physiology in many respects peculiar to itself, and which borders very closely on the pathologic, tending very easily to pass over into it. In a certain sense, the ordinary vomiting of pregnancy is to the uncontrollable form as the ordinary "physiological" jaundice of the new-born is to pernicious icterus neonatorum. Further, just as every woman brings with her into her pregnancy the results of her past pathological history, so the new-born infant brings with him, out of his antenatal life into his neonatal existence, the effects of any morbid processes which may have attacked him *in utero*. In this way the pathology of pregnancy and the maladies of the new-born infant are both invested with peculiarities. The peculiarities, therefore, of neonatal diseases are not inexplicable, but are the direct outcome of the action of the antenatal and intranatal factors on the organism at this period of life.

J. BERGEN OGDEN, M.D., SECRETARY.

REGULAR meeting, Wednesday, November 15, 1899, DR. H. F. VICKERY in the chair.

DR. R. F. CHASE reported

A CASE OF BRADYCARDIA.[1]

DR. KNIGHT: The case reported is a very interesting one. The slowest pulse I remember in a case of valvular disease was in one of aortic disease after compensation was lost, when the patient was within a few days of death, and for a few days the pulse would

[1] See page 139 of the Journal.

beat either at the rate of 18 or at a very much higher rate. I have forgotten exactly what the higher rate was. There was a regular alternation. It would go along at the rate of 18 for several hours and then change to the higher rate and go on again several hours and then back again, and pursued that course several days until the patient died. I think that is the lowest I have ever counted — 18. There are cases on record where it has gone a good deal lower than that.

DR. TWOMBLY: I saw the case with Dr. Chase on March 11th, and at that time I counted the pulse very carefully; it was 28. There was also a very slight systolic murmur at the apex. It was not remarkable and you would not notice it unless you listened pretty carefully for it, but having had my attention called to the fact that there had been one, I naturally made a careful examination, and found it unmistakably present. How long the murmur had been there, or to what extent it had exerted any effect on the slowing of the pulse, I think it is very difficult to say. Dr. Chase has watched this case very carefully, and obtained a good many records of the pulse rate, and in no case, he says, has it been over 36 per minute. I wish he had drawn the inferences, which I hoped he would make, of the relation of this slow pulse to age. We know that there are different forms, one of which is a temporary slow pulse which gradually resumes its natural number of beats. I have seen it in the case of a growing boy who had a great deal of malaria, when the pulse was down to 40, but that condition was not permanent. When we get it in the cases of old men, the continuance of a very slow pulse like this must be thought of and regarded as a very dangerous condition and the prognosis is a very grave one. If we look up the literature we find very few such cases. In those that have been seen and reported, it has been found that old men, where there is not the temporary but the permanent bradycardia, live but a short time, dying within one or two years after observation, and even at a shorter period. It certainly is an instructive case; because we had an old man, looking very well, jolly and seemingly very comfortable, and yet there was that condition which, when he had walked a little way to his daughter's house, resulted in the fatal overtaxing of the heart muscles.

DR. WHITTIER: This subject presents one of the most remarkable, as well as one of the most undesirable forms of abnormal variation in pulse rate, one that will always offer to the clinician problems of the most perplexing type. Whether the abstract condition is constant or paroxysmal, physiological or pathological, a reflex of diseased or disordered action in other functions, notably of the digestive apparatus, or associated with arterial scleroses, with myocardial changes, or with unmistakable evidences of valvular disease, whether arising from chronic intoxications from lead, alcohol, or renal disease, or in connection with acute infections, etc., there will remain a very considerable percentage of cases wholly unassignable to changes appreciable during life, or discoverable after death.

Slow pulse, constant or paroxysmal, should be regarded with great apprehension; seemingly, it is more frequently connected with organic disease, particularly with disease of the coronary arteries or of the myocardium, than tachycardia is. I believe that life insurance companies will accept risks with a high pulse more readily than they will those classified as bradycardiacs; slow pulse, more frequently than rapid, influences "expectancy of life." It is extremely difficult to demonstrate the physiological origin of bradycardia; its association with pathological processes is much closer and more intimate than is generally thought. Sub-standard pulse rate is much more to be dreaded than super-standard; it is relatively infrequent, experience shows it to be rarely met with, and when seen does not receive the attention its harmful influence commands and should render imperative. We are inclined to underestimate the significance of abnormal slow pulse, excepting in connection with structural changes, and then more attention is paid to the supposed cause, which may range from catarrhal jaundice to long-standing intestinal disease, cardiac, renal, hepatic, etc. This frequent association of bradycardiac and organic disease leads us to regard as unimportant the abnormal slow pulse of undetermined origin. It is needful, in all these cases, to exercise special care in the examination of the patient and to determine the question of uniformity of radial and cardiac pulse. I have seen, recently, a difference of 24 between wrist and apex and remember well a case of paroxysmal and slow pulse, not irregular nor intermitting, but regular at one-half the apex rate. These cases must be regarded with extreme apprehension, for the condition is grave wherein the ventricular contraction is so insufficient and incomplete as to fail to transmit pulse wave to the radials.

I somewhat hoped the subject of rapid heart would be included in the paper presented, for there seems to be larger interest in the aspect of abnormal heart rates — it may be because people survive the influences of high rate and prolonged rapid action exceeding all our preconceived opinion of the heart's endurance. The most energetic and, in most regards, the most interesting member of this group, is paroxysmal tachycardia of the functional neurosal type. In such cases the pulse rate, without warning or appreciable cause, by quick strides reaches a rate seemingly far beyond the limit of more than very few hours of cardiac action, and yet, I think the Massachusetts General Hospital records show a case of pulse rate of 180 or more during twenty-seven consecutive days.

I followed for a number of years a gentleman, whose first attack, of thirteen hours' duration, gave a pulse rate of 200 to 210. Dr. Ellis saw him in consultation and gave a lethal prognosis, immediate and from cardiac exhaustion; however, the patient survived not only the initial and exceptionally prolonged paroxysm, but also numberless similar paroxysms, covering several years and finally died of malignant disease of the lower bowel. The sphygmograph seemed to offer the only explanation of the heart's tolerance of such rapid movement, for in this and in other cases, from 178 to 200 pulse rate, the pulse was of low tension and the expenditure of energy as shown by the height of the primary wave was not more than one-third normal. The tracings submitted to us this evening are evidently of high arterial resistance and some of the primary waves are so short and other elements so defective as to suggest impending cardiac collapse.

There may be preventive remedies for this class of cases, and it may be also that there are palliative measures fairly constant in their effect, but of one thing I am certain, that is, that digitalis is dangerous;

it seems to make the patient somewhat more comfortable, but I believe that it shortens the period of the heart's viability in all cases where tachycardia or bradycardia is an element in organic disease, notably of the myocardium. Strychnia, however, in combination or alternating with nitroglycerin, offers the best promise of assistance.

DR. J. W. COURTNEY read a paper entitled

A CASE OF MULTIPLE CEREBRAL HEMORRHAGES FROM CHRONIC LEAD POISONING, WITH NECROPSY.[2]

DR. PRATT: I have been fortunate to make the autopsy in two cases of hemorrhage into the pons; this case of Dr. Courtney's and one that occurred at the City Hospital last spring. There have been 26 cases of cerebral hemorrhage among the 1,138 autopsies performed at the Boston City Hospital since January 1, 1896. The case just mentioned was the only one in which the hemorrhage involved the pons. The subject was a man of forty-five. Singularly enough, he also was a painter by trade. There was marked arteriosclerosis, chronic interstitial nephritis and hypertrophy of the heart. The hemorrhage was a centimetre and a half long and five millimetres in its greatest width. Unfortunately, the hemorrhage took place in the early morning hours and the character of the convulsions which occurred was not carefully observed. He died a few hours later.

Gowers states that the hemorrhage is often spherical in shape. In both of our cases it was fusiform, with the long axis extending longitudinally through the center of the pons. This agrees with the description von Monakow gives in Nothnagel's "System." Bode collected 78 cases of hemorrhage into the pons. In 46, death occurred within 24 hours.

Relative to the size of the hemorrhage, it may be interesting to state that, according to von Monakow, it varies from a hemp-seed to a walnut. The hemorrhage in Dr. Courtney's case measured 1.6 centimetres in length and two to nine millimetres in width.

DR. V. Y. BOWDITCH read a paper entitled

THE MASSACHUSETTS STATE HOSPITAL FOR CONSUMPTIVES AT RUTLAND; ITS PURPOSE AND THE WORK ACCOMPLISHED DURING ITS FIRST YEAR.[3]

DR. KNIGHT: It is hardly necessary to say much to this audience in favor of sanitarium treatment of this disease. I wish some of us might have an opportunity, in some way, perhaps to approach the public. However, that will be done by the reports of the work of this institution and by the necessary work which will have to be done before the Legislature. I am very proud certainly that our State was the first to undertake this work and of the little part which I had in it. The whole question of treatment of disease in this way has developed gradually of course, largely through the initiatory work of Brehmer, but still I think, aside from that, that the experience in hospitals, in homes for consumption which were supposed to be for incurables, and the result in general hospitals of patients getting well who had undoubted tuberculosis, turned attention in that direction. I remember in Bellevue Hospital years ago, when I was assistant to Dr. Flint, he said that patients with tuberculosis who came into the hospital all improved wonderfully. It did not make much difference whether we gave cod-liver oil or something else. A ward was set apart for patients to whom no medicine was given, but good diet, etc., and he found they improved just the same. The food and regular life and hygiene in every way put them on the road to improvement and recovery in some cases, and so in the hospitals for consumption, the homes all over the world, in Brompton and in the others, there have been cases of cure. I have been interested in seeing in a recent work an enumeration of the homes, hospitals and sanitaria of all kinds for tuberculosis, and finding that in this country we stood pretty well up in the list. Germany has the largest number, something over 40, of homes and sanitaria for tuberculosis, and the United States between 30 and 40, France 20 odd, and England 20 odd; but now the institutions which have been starting up for the last ten or twelve years in almost all the countries of Europe, particularly in Germany, also an excellent one just out of Vienna, under the direction of Professor Schroeter, also one in Italy, and in most of the countries, in fact, are more on the plan of the strict sanitarium where patients are under constant supervision and proper treatment.

I agree entirely with what Dr. Bowditch says, that a patient has a great deal better chance of recovery from tuberculosis in a sanitarium than in private life, no matter how rich he may be. It is the one disease which of all others requires constant watchfulness on the part of somebody who understands it, and I have hoped that in these institutions a class of nurses will come up with whom we can trust our patients, who will understand the general management of them so that well-to-do patients who want to travel can do so with safety with these educated attendants. I had a very good illustration this summer of what may happen to a patient who is going on his own responsibility. A gentleman, who had followed rules very carefully, had gone on for about two years struggling very successfully against tubercular disease, had been perfectly willing to live the life which I advised, but he felt that he was obliged to attend to his business, with a certain amount of recreation in the summer. I happened to be in a hotel with him this summer. I think it was great good fortune that I was. He came to me one day and said: "I feel chilly and uncomfortable and I think I will go and take a long horseback ride and see if I can sweat it out." I directed him to go to bed. I found he had a very high temperature brought on by over-exercise. He thought that if he rode horseback ten miles it might do him more good to ride twenty or thirty. I kept him in bed ten days and his fever left him entirely and he recovered from that setback, but his pulse did not become normal until to-day. To-day for the first time he has a normal pulse. Fortunately there was no lighting up of the pulmonary disease. He had an attack of fever which lasted ten to fourteen days, and weakness afterward, but recovered. If I had not been there, I think he would have had a very much more serious time, perhaps been put back fatally. There was a man doing his best on his own responsibility; if he had been in a sanitarium that would not have happened.

I think that we all can do perhaps better than we have done, not only in putting patients in a sanitarium, but in beginning treatment of whatever kind earlier; not only finding out the disease ourselves, and admitting it to ourselves in an earlier stage, but also as a rule telling the patient the gravity of the situation. The patient will not do what he ought to do unless he

[2] See page 136 of the Journal.
[3] See page 127 of the Journal.

comprehends the seriousness of the affection, but I have never found any ill effect from making the patient aware of his condition. Even Hippocrates says, if you treat the consumptive patient in the beginning he will get well. What I mean by early is to take the patient within a few weeks of the beginning of his cough, before he seems sick, before his friends feel that he is ill at all, as soon as the nature of the affection is determined. The majority of patients I have sent to Colorado, where I have had a great many recover, have been patients who seemed well when they went and seemed well there, nobody mistrusting they were sick. That is the time to send them. I had a consultation a few weeks ago with a physician in the neighborhood. He had a patient who began to cough last spring and various things had been suggested for relief. He went on from bad to worse. In the conversation I had with this physician he said: "I haven't much faith in the treatment of these cases." Suddenly he started up and said: "Perhaps I don't get hold of them soon enough." That is the whole business. If we can send patients into sanitaria within five or six weeks of the recognition of trouble, as we often can, if we take the trouble to thoroughly investigate, especially now that we can examine the sputum, we will get recovery in a very large proportion of cases.

Dr. Otis: I am sure that Dr. Bowditch, in thus presenting so admirably his year's experience and results at Rutland, has done to the profession as well as to the laity of the State an invaluable service. There are many of the profession still, I fear, who are unappreciative of the very great advantages of the hygienic-dietetic treatment of phthisis and the systematic methods of enforcing it in vogue in this sanitarium, and it will be a long time yet before they are fully realized both by physicians and the people. Only this morning an intelligent gentleman was in my office who had incipient pulmonary tuberculosis, and as I was explaining to him the plan of life he should pursue and the importance of outdoor air night and day, he seemed surprised and remarked: "Why, doctor, I thought I had to keep indoors with this disease," and I have no doubt that he illustrates the ideas of many consumptives regarding the management of their disease. I remember Dr. Baldwin, of Saranac Lake, told me of a young woman whose disease had been arrested at the Adirondack Cottage Sanitarium, and who, on her return to her home in Hartford, Conn., continued the habit she had learned at Saranac of sitting out of doors, even during the winter, much to the astonishment and horror of her neighbors, who looked for some untoward event in consequence. She remained well, however, and was the better for her daily and long-continued doses of outdoor air.

Dr. Bowditch has referred to the educative effect of the sanitarium treatment, and this, I believe, is of very great value. The patients become apostles when they return home and preach to others of the hygienic measures by which they have been cured; of the value of pure air by night and day; of the avoidance of overheated and ill-ventilated rooms; of the value of good food and the care of the sputum — such personal influence must be of very great importance in the prevention of the disease.

The best results of sanitarium treatment which up to the present time have been presented are, I think, those of Dr. Turban, of Davos, Switzerland, which he has published this year. Of 408 cases dismissed from his sanitarium, he reports 66.1 per cent. relatively or absolutely cured, and of these, 97.6 per cent. were of the first stage, 73.2 per cent. of the second, and 23.6 per cent. of the third. Subsequently he communicated with these cases who had been out of the sanitarium from one to seven years, and he found that 48 per cent. of the whole number remained relatively or absolutely cured, as attested by a physician's examination, and of these 80.4 per cent. were of the first stage, 48.8 per cent. of the second, and 17 per cent. of the third; surely most excellent results. Dr. Bowditch, in his 114 cases, shows wonderfully good results also, and without the advantages of the high altitude climate as in Turban's cases. Such results could not have been obtained, I believe, either in this or any climate *outside* of a sanitarium.

There are a number of problems which the sanitarium movement brings up. One sanitarium in a State like this is only a beginning, and I fully believe that when the value of the Rutland institution is fully appreciated others will be demanded by the people, and some of them for a rather different class of persons, I hope, from those the Rutland Sanitarium now receives. Looking at the photographs of the Rutland inmates you notice they represent a refined class of people. The worthy working class who, when they are obliged to give up their occupation, become penniless, ought to have an opportunity for *free* sanitarium treatment. Fifty cents a day is as impossible for them as five dollars a day. This class — the working people — is a very important and large one, and provision for sanitarium treatment should be made possible for them. We need, indeed, in many of our well-known health resorts such carefully conducted institutions as the one at Rutland, to which we can with assurance send our well-to-do patients. If we were assured that at Colorado Springs, for example, there existed an institution as admirably conducted as Dr. Bowditch's at Rutland, we should feel greater security in having our patients in them and expect better results than from the so-called open-air treatment, which is often a go-as-you-please one. I remember at the last meeting of the American Climatological Association, one of the gentlemen read a paper upon the management of patients in Colorado, and on being asked how many hours a day he was able to keep his patients out of doors, replied, only about five and one-half hours in winter, on account of the difficulty of exercising proper control over them. With the magnificent climate in Colorado, under the direction and control of a sanitarium, we ought to expect equally favorable results as those at Davos.

With regard to gymnastics, to which Dr. Bowditch has referred, I desire to utter a word of caution regarding their use, as indeed of all exercise. It is well to bear in mind that in the treatment of phthisis overexertion is to be strenuously avoided, and in certain conditions, as the febrile, all exercise is to be interdicted, as Dr. Knight's illustration has just shown us. Every diseased organ needs rest in order to recover itself, as Dettweiler has so well shown in the case of the lungs. I do not wish to be understood as opposing lung gymnastics; I consider them a valuable adjunct in treatment, only the cases must be selected with the skill and care which Dr. Bowditch exercises with his. With regard to the length of stay in the sanitarium, it should be long enough to obtain the best results. With the 408 cases of Turban's the average residence was

two hundred and twenty-five days, about seven months. Dr. Bowditch's cases averaged four months, and in the sanitaria for the poor in Germany, according to Cornet's recent statement, the average was only about three months. Cornet does not regard this as long enough to obtain the best results, but it seemed to be a pecuniary necessity. Once having established free sanitaria for the poor, it would be a pity and poor economy to dismiss a patient before he had obtained the maximum of benefit the sanitarium is capable of affording him. Another very important problem is the matter of proper occupation for a patient after he leaves the sanitarium, to which Dr. Bowditch has referred. A great many cases come from unwholesome, indoor occupations, to which they ought not to return if they are to maintain their restored health; and in some way they must be aided in securing work which will be wholesome and if possible keep them out of doors. Some association perhaps might be found to accomplish this. Then, again, when you have a sanitarium for the laboring people, some arrangement for the support of their families must be made while the bread-winner is being cured and so taken away from his work which sustains his family. What a common occurrence it is for the poor consumptive to continue at his occupation almost as long as he can stand up, and thus destroying his chances of recovery or arrest.

These are some of the problems which will come up for consideration and solution in connection with sanitarium treatment; but I do believe that the great wave of enthusiasm which is spreading over the civilized world, in England of late especially, and beginning also in this country, in favor of sanitaria as affording the best and most hopeful treatment for phthisis, especially for the poor, will continue, and that the authorities of the different States will recognize that it is an economic measure as well as a philanthropic one to restore to their occupation and usefulness, through sanitarium treatment at public expense, the thousands who would otherwise become a burden sooner or later to the State.

DR. WORCESTER: I am only too glad to have the chance to endorse all that has been said, and at the same time I am glad of the chance to point out some of the difficulties the institution has had in starting. It was my fortune to be one of the trustees appointed to establish the hospital, but I am no longer a trustee, and so perhaps am more free to tell some of the woes and miseries which my former colleagues on the board must still endure. The hospital cost more than the Legislature appropriated, and that was in part due to our ignorance. We did not know how impossible it was to build a complete hospital with the money the Legislature allowed. Had we known more, however, and undertaken less we should not have had the institution at all. Now the trustees are again in somewhat the same predicament; the appropriations this year are not sufficient to pay the running expenses and it will be necessary for the trustees to ask for a larger grant this year and also a grant to make up the deficiency. How far the popular enthusiasm which now seems to exist for the hospital will come to the rescue of the trustees and carry them through I do not know, but I imagine that the friends of the hospital, the medical profession especially, which is most competent to recognize the good of it, will have to put a pretty generous shoulder to the wheel to carry the thing through. The hospital will hold only 200 at most, and it was full, as Dr. Bowditch says, within a few months, so there is no use in our thinking of it, except as a splendid practical illustration of what may be done in fighting tuberculosis. We have got to have many other such institutions scattered through the State. We have got to put a hundred times more effort into this business than has yet been put.

I cannot help drifting from Rutland and speaking a little of similar work I have tried to do in Waltham. It certainly has taught me what may be done and ought to be done. Before the Rutland institution was started I undertook to take consumptive patients into our little general hospital, which has only sixty beds, and there I obtained results strikingly successful. I think now this result was largely due, as Dr. Bowditch at the time pointed out, to the hygienic surroundings. Those patients were certainly stuffed with eggs and beef and milk and had all the fresh air there was, and they certainly did well; but after going back to their homes most of them did very poorly. Now what is the use, it may be asked, of getting a man or woman built up in any of these institutions and letting them go back to the conditions in which they were before? They may live a year or two longer, but then they have been away from their families a year or two. It is very easy to be a pessimist in the matter, but it is also possible to be an optimist. It is not necessary that they should go back into the same unhygienic conditions, and care must be taken of them in some organized systematic way. I have heard of an Irishman who left the Rutland hospital, and trouble arose between him and his wife because he insisted upon sleeping with the windows open. That illustrates one difficulty.

And then I have sometimes questioned if it is a real benefit to separate families as much as is necessary if going out of the county and miles away is a necessary part of the programme; but it is a very different thing if the sanitarium treatment can be employed in the town where the patient lives. Of course, it is an advantage to a patient to leave the low altitude of Boston and all this dreadful air that so many of you have to breathe, and go out into the country, but it is not necessary to go as far as Rutland. Even if there is such a great advantage in breathing higher air and living in it there is a corresponding depression in returning to one's home. I have always felt it was no special advantage to send a person to Colorado who could not have his family go with him, because it is so seldom possible for a patient to come back and live here. If the same horseback riding and outdoor life was employed in Massachusetts that is fashionable in Colorado Springs, would not a great many who have received benefit there have been also benefited had they stayed here and gone through the same régime? If we can only persuade people who are afflicted with tuberculosis that it is absolutely indispensable that they shall have everything that is nourishing in the way of food and any amount of oxygen, and if we can persuade them to carry out that régime here, I think in all ways it is very much better. Of course the little sanitaria started through the State will do much to teach people. But there must be a sanitarium in each town and city to teach the people in the towns and cities what to do. It is all very well to read reports about this work, but the many will never see or hear about it, and so we shall go on as

we have been going on unless the medical profession rises from its apathy. It seems to me, gentlemen, that the medical profession is most blamable in the treatment of tuberculosis. I am ashamed of myself to think how many times I have neglected a consumptive. There has been more lying on the part of the medical profession in regard to consumption, I believe, than can ever be atoned for. We know how easily we shift them off. The first time we think it is not so, and after we think it is so, we think it is not best to tell them so, and then we go through the farce of discussing with a relative whether it is best to tell the patient. I am thankful to hear Dr. Knight speak so emphatically as he has upon that subject. If the truth can only come into the treatment at the start, it will do a large part of good we trust later to obtain from oxygen and higher altitudes.

And now I cannot help adding that it is not enough to fold our hands and trust to fresh air and good food and give up all idea of other therapeutic agents. Hygiene is all well enough in its way, but it is merely an adjunct in the treatment of tuberculosis, and no matter how unpopular the subject is, I believe that in the use of tuberculin we are yet to find the proper treatment of that disease. I have used it year after year and I believe in it more and more, and I wish very much that instead of trying some of the serums that never will amount to anything anyway, there might be, in some of the hospitals devoted to the treatment of tuberculosis, a chance of carrying out systematically and thoroughly the experimentation that is going on and has been going on all these years in the wards of the Charité in Berlin. It is only too sadly true that tuberculin is an exceedingly dangerous thing to meddle with, and that there has been a great deal of mischief done in the ignorant use of it, and then we have only just lately found out that the tuberculins we have been using have been made from different varieties of the tuberculous germs, which have very different effects. There is great difference in the effect of tuberculin made from the bovine tuberculous germ and from the human tuberculous germ. The tuberculin from the bovine produces very much less reaction in man. I am one of those who believe that human tuberculosis never came from bovine tuberculosis any more than variola ever came from vaccinia. When you see, as you can see in Prof. Theobald Smith's work, the morphological and physiological differences of the different species or varieties of the tuberculosis bacillus, and when you realize that until recently we have had no means of standardizing tuberculin, no one can wonder at the very varying results that we have had. I never shall allow myself to be caught on my feet in speaking about the treatment of tuberculosis without insisting that the medical profession must yet listen to the claims of the treatment of the disease by tuberculin.

Dr. Getchell: Speaking as a trustee I can only reiterate and emphasize what Dr. Knight has said. This year we shall be obliged to go before the Legislature with a deficit, and also a request for considerable sums of money for what seems to us to be absolutely necessary additions. The law called for an institution that should accommodate 200 patients. As Dr. Bowditch has said, under the contingencies of the additional expense that could not be foreseen the accommodations were curtailed, so that a part of the hospital that was intended for patients has been occupied by nurses and other members of the administration force; and the hospital is not doing the work that it should do. As you will see by the report, which will be placed in the hands of every physician in the State, an attempt will be made to remedy this by providing a dining-room which will relieve the rectangular buildings at the rear of the hospital, and which will give accommodation for servants and will enable those rooms to be used for patients. There will be another question which will arise in the Legislature, and it has already arisen, and that is the question of enlarging the hospital beyond the capacity for 200, and it is here we want and need the aid of every physician in the State that the Legislature may understand what the hospital is for. I am perfectly sure that many of them look upon the institution as an institution that is analogous to the insane asylum — that is an institution built by the State and for State charges. As a matter of fact, the people who come to the sanitarium are not State charges. The majority of them are people who have been earning their livelihood at the time of their admission or just previous to it, and as time goes on and the matters that have been brought forward to-night are recognized more clearly, the disease will be detected earlier by physicians, and the number of people who are earning their livelihood will be much greater. It is very important indeed, I think, that the Legislature should recognize this, and for help we look to the profession.

We find in the papers a good deal about the State aid for consumptives. Now it seems to me, that that is the best attitude for us to take at present in the matter. The people who come to Rutland only pay one-half of the actual cost. It costs some over $8.00 a week for each patient and the charge, at first $3.50, is now $4.00, and it seems to me, the idea ought to be as widely disseminated as possible that this sanitarium is built by the State as an aid and not necessarily as a place where people go and will be kept at the expense of the State. Under the present methods of administration, more than 200 patients cannot properly be cared for and unless the institution depart from the sanitarium idea it should not be enlarged. We are behind in our current expenses. The request was made of the last Legislature for $40,000 for current expenses, and at that time I think it was felt the hospital would not be filled as readily as it was. In February the full capacity was reached and the hospital has been full ever since. Furthermore, there were necessary expenses and those expenses have been taken from the current expense appropriation, ordinary repairs, matters that could not be neglected; so that I think at this time the appropriation is exhausted and a deficit is accumulating month after month. There has been the utmost attempt to economize. I think I am not divulging any secrets of the board when I speak of the difficulties that we have had this summer in regard to the matter of food. The administration has been between the two fires of insufficiency of means and the attempt to economize particularly on that most vital of all articles of food in a sanitarium, eggs, a matter in which undue economy is of doubtful wisdom. I have no doubt of the outcome. The Legislature of Massachusetts, when it has felt an expenditure for public purposes to be necessary, has always granted the means, but I do feel that every avenue of information will have to be used this year in order to enable the institution to go forward

with the work that it has, without question, very satisfactorily begun.

DR. PERCY: It seems to me it is hardly necessary to add anything to what Dr. Getchell has already said, but it has occurred to me as I listened to Dr. Bowditch's very interesting report that one thing he has omitted to say, and that is that another question may be solved and solved in a very short time in regard to the statistics of our hospital, and that is verifying a suspicion or an opinion which is entertained by a great many men now, that cases which are arrested in their environment are much more likely to remain so than cases where the disease is arrested elsewhere, and they return to their former environment. That is a very interesting problem the State is trying to solve, and, it seems to me, is bound to solve, and I feel confident the answer is to be a favorable one. Dr. Otis has asked several questions to-night and I feel deeply grateful to him for doing so. Among them, no problem has been more serious than the one in regard to the occupation of these people who come out apparently restored to health, and it is a matter still under very serious consideration. It may be met in a variety of ways, but, it seems to me, it must come by co-operation on the part of people interested, and if a corps of workers can be organized who will have the interest of those people at heart, we shall be able to do far better for them, and shall be able for the first year to provide for them in a way which is certainly in their favor. Another thing which constantly comes to the trustees is this problem in regard to children. No problem, the superintendent said this week, had vexed him more than what should be done with a little girl who came from the North End of Boston, who is absolutely restored to health and has absolutely no place to go. With regard to the children of mothers who are there, and who naturally have a very deep interest in them and are very lonesome without them, they are provided for in boarding-houses in Rutland. Already a nurse of the kind Dr. Knight spoke of, who has been trained in sanitarium methods, has opened in Rutland a home for cases not admissible to the hospital, where people can be sent with the idea of doing for them what cannot be done at any other place.

DR. BANCROFT: The city of Boston is making a move in this direction, but limited to a very small field. At Deer Island there is an institution where all tuberculous prisoners from the prisons of the city can be assembled in one building, that place being so situated that they can be kept out of doors as the circumstances demand. Then our two prisons will be freed, so far as the cell occupants go, of tuberculous cases, which is impossible now.

DR. BOWDITCH: In speaking of incipient cases, I am much struck with the fact that so many patients are sent for examination as incipient cases, merely because there are comparatively few signs in the chest. No regard seems to have been paid to the presence of a rapid pulse, high temperature and often bad digestion. Such cases are most unfavorable for treatment as a rule, and usually show the symptoms later of a general tuberculosis. The non-febrile cases are much to be preferred in any attempt to bring about an arrest of disease.

As to the necessity of caution in pulmonary gymnastics, too much stress cannot be laid upon this point. At Rutland classes are formed for this kind of exercise, but it is not used when, for any reason, rest seems indicated. For the sake of making variety for the patients, even baseball is resorted to, but with caution, and only the most vigorous are allowed to take part. In the past six or eight months, in consequence of the precautions taken, I know of no case that has received any injury from this form of exercise. Golf is now in use with excellent effect both on the mental and physical condition of the patients.

Dr. Worcester has spoken of the use of tuberculin therapeutically. He knows the respect that I feel for his views upon any subject, and yet on this point we have been, as it were, at the opposite ends of the pole on that question. Even as to its use diagnostically, I have held, as stated in this room several months ago, what may be an ultra-conservative position, because I was not convinced of its absolute innocuousness. From that position I have retreated somewhat, having felt that in a few cases I was justified in its use where other means failed and a definite diagnosis was imperative. As to its use therapeutically I am still a skeptic, although glad and willing to be convinced when absolute proof is given me. Dr. Worcester has spoken himself of the marked variation in the strength of the different preparations and under these conditions the indiscriminate use of the substance, except by those who have a knowledge of bacteriology, seems to me wrong. Under present conditions, with the means at our command, I should be unwilling to use the substance, unless more fully convinced of its efficacy.

Recent Literature.

Pyorrhea Alveolaris and its Relations to General Medicine. By JOHN FITZGERALD, L.D.S., Dental Surgeon to the Italian Hospital and to the National Hospital for Diseases of the Heart and Paralysis, Soho Square. London: The Medical Publishing Co., Ltd. 1899.

The author states in his preface that the object of this little book is to point out the bearings of this disease upon medical practice and to indicate simple methods of treatment within the reach of the family physician.

The book is interesting from many points of view and contains many valuable suggestions for the diagnosis and treatment of this truly formidable disease. Attention is called to the secretion of the gingival organ and the importance of not mistaking this secretion for pus. The effect of mal-occlusion of the teeth is pointed out, although hardly enough importance is given to this as one of the predisposing causes of the disease.

We are inclined to believe that the presence of lactic acid in sufficient amount to have any serious bearing upon the disease is not sufficiently proven. It is also doubtful if the invasion of the pockets at the sides of the roots can be called a "streptococcus" invasion, as the observations of bacteriologists in this country would tend to show that the staphylococcus forms only are generally found in these pockets and are probably responsible for the production of pus.

The author has evidently not too high an opinion of the ability of the average dentist to treat this disease and has a somewhat exalted opinion of the tech-

nical skill of the average medical practitioner. He gives directions for the treatment of the disease by the physician, and gives a list of the instruments likely to be required in the course of treatment, and in doing this we think that the author has rendered his work almost valueless.

The amount of time and training that would be required to train the average physician to recognize the varying aspects of the disease and to use the necessary instruments with proper skill would not be less than the training which would be necessary to render the average dentist competent to perform an operation for appendicitis.

While we believe that the attention of the physician should be called to the importance of an early diagnosis of pyorrhea alveolaris we are equally confident that its operative treatment should be left in the hands of the dentist.

Diseases of Women. A Treatise on the Principles and Practice of Gynecology, for Students and Practitioners. By E. C. Dudley, A.M., M.D. Second edition, revised and enlarged. Philadelphia and New York: Lea Brothers & Co. 1899.

The publishers' part of this second edition of a book which has now become standard is admirably done. The text is clear, the plates numerous and admirable. The arrangement is very original, and at first strikes one as odd, but after reading the book through it becomes evident that it is admirably natural, leading the reader easily from one subject to another, and that it is extremely easy to find any subject which one wishes to look up. It is especially unique in one respect. It combines the careful treatment of detail which is characteristic of the older type of book, such as Emmet's and Thomas's gynecologies, with all the advantages of the modern operative school, in which latter respect it is fully up to date. One feels too often after reading the recent text-books that the author is a surgeon rather than a man equipped with a specialist's knowledge of the diseases of the female pelvis. This book is written by perhaps the most scholarly of American gynecologists, and shows it on every page. Each disease or lesion is treated in the most thorough way from the standpoint of the mechanical relations and pathology, before treatment is taken up. In spite of its being limited to but seven hundred pages, it is encyclopedic in its thoroughness and completeness.

Part I, devoted to General Principles, is admirable in the clearness and detail of the descriptions which it furnishes for a beginner. In Part II, on Inflammatory Infections, the chapter on Pelvic Cellulitis is especially timely. That on the Treatment of Salpingitis, Ovaritis, and Pelvic Peritonitis is very thorough and useful. In Part III, devoted to New Growths and Malformations, the pathology is remarkably clear, the directions for diagnosis good. In Part IV, Traumatisms, the descriptions of the lacerations of the perineum and cervix and their method of repair are most remarkably clear and good. Every beginner may learn from them how the operations should be done, while even the expert may learn something of value from reading them. Part V, upon Displacements, is thoroughly up to date, and is supplemented by an admirable chapter on Massage. Part VI, upon Disorders of Menstruation and Sterility, treats this complicated subject wisely and conservatively.

The book as a whole is perhaps our best text-book.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, FEBRUARY 8, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

Subscription Terms: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 Washington Street, Boston, Mass.

THE EVOLUTION OF SURGERY IN LONDON.

The growth and evolution of the profession of surgery will always be a fascinating study, nothwithstanding the fact that it serves the profession as the Darwinian theory served the race in tracing it back to a humble origin. The part played by the barbers and the barber surgeons, not only in surgical practice but as an organized body, in London from the earliest times even to as late a period as 1745 cannot but excite surprise in the mind of the modern student of surgical history. A very readable pamphlet entitled, "How Surgery became a Profession in London," by D'Arcy Power, reprinted from the *Medical Magazine*, gives an account of the history of the surgical profession in London which is well worthy of a review.

In the Middle Ages there were two types of surgeon in London, "the military surgeon and his peaceful though often brawling brother, the barber surgeon. The military surgeons, who formed rather the aristocracy of the profession, were in attendance on the kings and nobles as early as the third Crusade, (1189–1192), and in the thirteenth century there were formal gradations of rank, such as Royal Surgeon, Common Surgeon," etc. A clear view of their status earlier than 1415, however, cannot be formed. In that year, when Henry IV crossed the Channel to conduct the campaign which ended in the battle of Agincourt he took with him his physician, Nicholas Colnay, and his surgeon, Thomas Morestede. These gentlemen, who had respectively medical and surgical charge of the king's army, received the munificent recompense of twelvepence a day, in addition to the usual allowance of one hundred marks to the quarter, the pay, it is stated, of thirty men-at-arms, with a share of the plunder. They were each attended by three archers as a guard, each of whom received sixpence a day. Morestede took with him a staff of twelve surgeons as his deputies and assistants, who received sixpence a day, or the pay of an archer. This scale of remuneration was very liberal, the wages of a day laborer at the time being one penny a day.

As a day laborer in London nowadays earns three shillings a day, while a surgeon on probation in the British Army receives only eight shillings a day, the assistant surgeons and archers in Morestede's time would receive, if paid at the present time in like proportion, eighteen shillings a day, beside their share of the booty. So it appears that military surgeons of the fifteenth century were better paid than those of the nineteenth.

Let us hope that the authorities of the twentieth century will take a lesson from those of the fifteenth, and increase the pittance paid to the surgeons in charge of the health and lives of their armies, a change sorely needed to attract a better class of men into a service the importance of which to military success has been for centuries unaccountably underestimated! Nothwithstanding the remuneration, however, the service was so perilous that Morestede had such difficulty in securing twelve suitable assistants that he requested the king for authority to press twelve qualified men into the service.

A Guild of Surgeons, as distinguished from the Guild of Barbers, existed in London from time immemorial, but was first incorporated, apparently, in 1369, and occasionally harassed the members of the Barbers' Guild, who meddled with surgery to such an extent that in 1410 "certain good and honest folk, barbers of the city," appeared before the aldermen and demanded that "they peaceably enjoy their privilege, without the scrutiny of any person of other trade than barbers. And this neither in shaving, cupping, bleeding nor anything in any way pertaining to barbery or to such practice of surgery as is now used or in future to be used within the craft of said barbers."

The movement for a complete medical education, together with a more effective control over the practitioners of medicine and surgery, began in 1423, with a petition of the Mayor and Aldermen of London, praying that physicians and surgeons practising in London might be considered as a single body of men governed by a Rector of Medicine with the assistance of two surveyors of the Faculty of Physic, and two Masters of the Craft of Surgery. There was to be a common place of meeting, with rooms for examinations and lectures. . . . No surgeon was to be allowed to practise in London unless he had been examined by the Rector, the two Masters, and the majority of the Craft, and duly licensed by the Mayor and Aldermen. under penalty of one hundred shillings fine. A patient unable to pay a fee might appeal to the Rector and Masters in Surgery, who would assign him a good practitioner, "busy to take heed of him without expense."

For an account of the career of the distinguished Dr. Gilbert Kymer, the first Rector of Medicine, we must, for lack of space, refer our readers to the original article. This "Conjoint Faculty of Medicine and Surgery" was, while it lasted, formidable to the Guild of Barbers, but it probably lasted not longer than two years, after which the two bodies of physicians and surgeons each went their own way till 1435, when the surgeons appear as an established fellowship, with a code of laws for its government. Thomas Morestede was one of the first seventeen members agreeing to the ordinances of the fellowship. In 1462 the guild obtained a charter of incorporation, and in 1492 received a grant of arms. In 1493 it was on friendly terms with the Barbers' Company, and in May of that year entered into a composition with that body which recognized the independence of the two fellowships of "surgeons enfranchised within the City of London and of barber surgeons and surgeon barbers enfranchised within the said city." No more is heard of the Guild of Surgeons till 1540, when they were formally united with their old competitors to form the "United Barber Surgeons' Company."

In the years immediately preceding and following this consolidation surgery reached the lowest ebb, and was of no account as a profession, for an act of Parliament was passed allowing any quack to practise. Of the history of the little band of surgeons, Thomas Gale, William Cloues, John Halle, John Read and John Banester, who, working independently at first, afterward banded together to lift their profession from the mire, Power's article gives a most interesting account, full of anecdote and quotation, which is well worth reading as setting forth the difficulty of getting the public out of the hands of ignorant pretenders. It seems that members of nearly as many trades put themselves forward as practitioners of surgery as do at the present time. Master Cloues mentions painters, glaziers, tailors, joiners, cutters, cooks and chandlers, as well as "tinkers, tooth drawers, pedlers, ostlers, carters, porters, horse gelders, horse leeches, idiots, apple squires, broom-men, bawds, witches, conjurers, sooth-sayers and sow gelders, rogues, ratcatchers, runagates and proctors of spittle-houses, with other like rotten and stinking weeds which do in town and country without order, honesty or skill, daily abuse both physic and surgery," etc. The gradual elevation of the Barber Surgeons' Company through the efforts of such men as these whose histories are given, their establishment of public dissections and lectures, with a fine for non-attendance, make a story of surpassing interest.

The stories of John Woodall, who discovered during the Elizabethan era that lime juice was a preventive of scurvy, and of his effort to free the surgeons from the impositions of the physicians, of his successor, Richard Wiseman, of Cheselden, Sharp, Percival Pott and Hunter, bring the story down to 1745, at which time at last the surgeons seceded from the Barber Surgeons' Company, and the Surgeons' Company was organized. Surely it took time enough to free surgery from its tonsorial associations and place it on its feet as a profession. Cheselden had raised surgery as a manual art, Hunter left it richer in pathology, but to Pott our author gives the credit for the social improvement which took place during the Hanoverian

dynasty. At the beginning of the present century the higher rank of surgeons had been established in a social position, as is evidenced by the lives of Sir Astley Cooper, Sir William Lawrence and Sir Benjamin Brodie.

A brief review such as this can give but a slight idea of the interest and value of such a study of professional history as is embodied in Power's article, which will repay the reading by all who are interested in the story of the struggle of the surgical and medical professions from humble and obscure origin to the position in which they belong, a study which ought to be worth the while of every enlightened practitioner.

SANITARIUMS FOR TUBERCULOSIS.

The recognition of the fact that tuberculosis is a highly preventable and in many cases a curable disease has led to an entire change of front in the attitude of the community toward it. By degrees the air of hopelessness surrounding the tuberculous person has given place to quite a different feeling, and with this changed feeling has come the natural desire, first on the part of physicians and then on the part of legislators to take an active interest in the treatment of the afflicted class to which such a person belongs. As a consequence, institutions have come into existence for the rational treatment of tuberculosis, at first regarded with suspicion, but now rapidly being accepted as a most necessary part of the hospital system.

A new impetus has evidently been given to this tendency in New York State, first, through the report from a committee of the State Board of Charities, the details of which we have noted in another column, and secondly, through the discussion recently held at a meeting of the New York State Medical Society. The committee of the State Board of Charities strongly recommended the establishment of local sanitariums, as the most efficient means of combating the disease, rather than crowding tuberculosis patients into one or two large institutions, possibly at considerable distances from their homes. Such a plan appears possible, both from the point of view of expense and ease of management.

Inasmuch as the régime of the patients should be hygienic, fresh air and good food and a certain amount of medical supervision, it should not be difficult to establish relatively simple and yet adequate hospitals in the neighborhood of centres of population. Elaborate buildings are certainly not required, and the equipment of such a sanitarium need be of the simplest. With the subsidence of prejudice regarding hospitals and sanitariums there is small reason to fear that such institutions would not be patronized, particularly if a slight stimulus in the shape of a law regarding precautions against infection were applied.

Drs. E. O. Otis and Vincent Y. Bowditch both spoke at the meeting of the New York State Medical Society from their wide experience in the care and treatment of tuberculous patients. Dr. Otis alluded to the desirability of securing legislative action in regard to tuberculosis, thereby bringing the disease under State control, as has been done, in a measure at least, in Massachusetts. Dr. Bowditch described the excellent work now being done at the Rutland Hospital, an example which should certainly be quickly followed by other States.

Others who spoke, among whom was Dr. Baldwin, of Saranac, simply echoed the general feeling of encouragement regarding the treatment of the disease by modern common-sense methods. No doubt continued perseverance on the part of physicians will finally lead legislatures to the complete recognition of the folly of longer delay in adequately providing for the hospital care of all persons ill with tuberculosis.

MEDICAL NOTES.

Plague. — The St. Petersburg plague board reports that bubonic plague is prevalent in Assyr, Mecca and Jeddah, and that, accordingly, this year's Mussulman pilgrimage to Mesopotamia is to be prohibited. In a recent attempt to eradicate the centre of plague infection in Honolulu, the fire started in the Chinese quarter for this purpose, was for a time beyond control, and threatened the entire city. Instead of two city blocks, an area of thirteen blocks was finally burned before the fire could be brought under control. A report from Major Blair D. Taylor, United States Army, in regard to the progress of plague in Honolulu, dated January 15th states that up to that date there had been 34 cases, with 27 deaths. The following week there were 12 new cases and six deaths. Plague has disappeared from Kobe, Japan, but is active in Osaka, taking the form of a lung disease which proves very fatal. Thirty-nine cases have been reported.

Small-pox in the West. — It is reported that small-pox is assuming considerable proportions in several Western States, on account of the evasion of vaccination and the refusal to obey the orders of the health authorities, on the ground that compulsory vaccination is a restraint upon the liberties of the people. As a daily paper says, "Perhaps a good-sized epidemic there might be useful for educational purposes."

Sir Michael Foster a Candidate for Parliament. — According to *Science*, Sir Michael Foster, professor of physiology in the University of Cambridge, one of the secretaries of the Royal Society, and last year president of the British Association, has consented to become a candidate for the University of London's seat in Parliament, vacant by the elevation of Sir John Lubbock to the peerage.

The "Maryland Medical Journal." — This journal, for many years published as a weekly, will hereafter appear as a monthly, beginning with the January issue. It will be published in Baltimore and Washington, considerably increased in size and improved in appearance.

SECTION OF A FIELD HOSPITAL GIVEN BY AN AMERICAN. — An American, Mr. Van Alen, now resident in London, has offered to provide a complete section of a field hospital for service in South Africa under the superintendence of the British Army Medical Corps, and his offer has been accepted.

OSTEOPATHY IN GEORGIA. — At its recent session, the General Assembly of Georgia passed a bill legalizing the practice of osteopathy. In spite of considerable pressure the Governor vetoed the bill.

INCREASE OF CREMATIONS IN LONDON. — In 1885 three bodies were disposed of by the London Cremation Society. In 1898 the number had risen to 240.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, February 7, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 121, scarlatina 53, measles 38, typhoid fever 11, small-pox 1.

DIPHTHERIA AND SCARLET FEVER IN MASSACHUSETTS. — The prevalence of diphtheria in Newton is about the same as it has been for a week or more. Three cases of scarlet fever have recently developed in Medford. In West Springfield the diphtheria epidemic is regarded as serious; the situation will be investigated by the State Board of Health. In the last six months West Springfield has had ten times as many cases of diphtheria to each thousand inhabitants as Boston. An order has been issued by the Medford Board of Health closing the Tufts and Lincoln School buildings in the South Medford district, on account of diphtheria. The prevalence of diphtheria is hardly to be regarded as an epidemic, since there are only about 15 cases, and only three deaths have occurred in two weeks, but the residents of the district have refused to send their children to the schools.

MEETING OF THE NEWTON HOSPITAL CORPORATION. — The annual meeting of the Newton Hospital Corporation was held February 4th. The report showed in general a satisfactory condition of affairs. New wards and other additions have enabled the hospital to meet the increasing demands made upon it during the last year. There are now accommodations for 150 patients. Particularly useful have been the isolation wards for diphtheria and scarlet fever.

LINCOLN SCHOOL IN MALDEN, MASS., TO BE REOPENED. — Notice has been given by the Malden Board of Health that the Lincoln School would be reopened on Monday, February 5th. It has been closed for the past three weeks, owing to the prevalence of small-pox in a neighboring house. One patient has recovered and another is rapidly improving.

TYPHOID FEVER IN OUTLYING TOWNS. — Fifteen cases of typhoid fever are said to have appeared on the route of a certain milkman in Brockton, Mass. A careful investigation by the State Board of Health has shown that the recent outbreak of the disease at Norwood, Mass., was due to the pollution of well water in which milk cans were washed.

AMBULANCE FOR SMALL-POX SERVICE. — An ambulance ordered by the Boston Board of Health some time ago, exclusively for small-pox service, is completed and in commission.

NEW YORK.

INCREASE OF INSANE CRIMINALS. — In his annual report, submitted to the Legislature January 29th, State Superintendent of Prisons Collins calls attention to the increase in the number of insane criminals, and states that 719, nearly 200 more than the buildings were designed to accommodate, are now crowded into the hospital at Matteawan. The over-population of this institution he regards as a very urgent demand for the earliest possible completion of the new hospital at Dannemora, for which an additional appropriation is necessary. A peculiar fact referred to is that out of 85 criminals sent to the hospitals for the insane during the year 40 come from the Elmira Reformatory, nearly as many as from the three State prisons combined.

A STATE HOSPITAL FOR TUBERCULOSIS. — On January 31st a hearing was given at Albany, by the Senate Finance Committee and the Ways and Means Committee of the Assembly, for the discussion of the bill recently introduced calling for an appropriation of $200,000 for the purpose of establishing a State Hospital for the treatment of incipient pulmonary tuberculosis. Commissioner Stoddard of the State Board of Charities and a considerable number of other medical men were present, and among those who spoke was Dr. Otis, of Boston, who gave some account of the establishment and work of the State Hospital for Consumptives in Massachusetts.

NEW YORK DIET KITCHEN. — The twenty-seventh annual meeting of the New York Diet Kitchen Association for the Relief of the Sick Poor was held on January 17th. Among the speakers of the evening was Dr. A. Jacobi, who incidentally alluded in terms of warm praise to the good results of the free distribution of sterilized milk by Mr. Nathan Strauss, who had persisted in his philanthropic work regardless of the ingratitude of some and the hostile criticism of others.

Miscellany.

LOCAL SANITARIUMS FOR TUBERCULOSIS IN NEW YORK STATE.

A REPORT has just been made by a committee of the State Board of Charities, consisting of Harvey W. Putnam and Drs. Stephen Smith and E. V. Stoddard, which strongly recommends the establishment of local sanitariums as the most efficient means of combating the spread of tuberculosis. The argument advanced by the committee is somewhat as follows: Fresh, pure air is now declared to be the remedy for consumption. The question to determine is, how can the fresh air treatment be most effectually and eco-

nomically made available? No one familiar with the peculiar habits of those who believe themselves to be the victims of tuberculosis can doubt the absolute necessity of placing them under rigid medical supervision. Under the discipline of the hospital or sanitarium, they can be compelled to conform to a prescribed method of living, and hence these institutions are essential to the treatment of consumptive patients of the laboring class. By the multiplication of these institutions, so that every consumptive would either undergo treatment in a special hospital or in his house, the disease could not spread among the people, and would eventually be exterminated. We are no longer compelled to seek health resorts for consumptives in remote mountain districts. On the contrary, it is possible to find in or near every community locations which, with the addition of hygienic conditions that may be supplied, will prove suitable for the full development of the fresh air treatment. The report concludes by expressing the conviction that if the Legislature should enact a law on the general plan outlined, it would at once lead to the establishment of local hospitals near all the great centres of population, the beneficent results of which would stimulate the people of smaller communities to the creation of their own sanitaria.

THE WAR IN SOUTH AFRICA.[1]

The Battle of Tugela (Colenso).

Frederick Treves, F.R.C.S., consulting surgeon with the British forces, sends the following graphic statement to the *British Medical Journal:*

It was from Frere Camp that the army under General Buller started for the Tugela River. Frere is merely a station on the line of rail which traverses Natal, and as it consists only of some four houses, it can hardly be dignified by the name of hamlet. These few single-story houses had been thoroughly looted by the Boers, and in one of them — the station master's house — the General had his headquarters. Frere is simply a speck — a corrugated iron oasis — in the vast undulating plains of the veld. On the way to Ladysmith are a few large kopjes, from any one of which the line of the Tugela River can be seen, with the hills beyond occupied by the Boer entrenchments, and over them again the hills which dominate Ladysmith. There was no shade of any kind, and as the weather was exceptionally hot the camp was not precisely comfortable. The inconvenience of a continued sun-glare was intensified by constant clouds of brown dust and by the scarcity of water. On the other hand, the evenings were cool and the early mornings delightful.

The river which is reputed to "run" through Frere had long since ceased to run. The water was retained by certain dams, and the pools thus formed were not over numerous. The water was the color of pea soup, and when in a glass was semi-opaque and of a faint brownish color. It soon blocked a Berkefeld filter, the pencil of which had to be cleaned after each water bottle had been pumped full. The filtered water was pleasant enough to the taste. In the lowest pool, immediately above the iron railway bridge which had been blown up by the Boers, Tommy Atkins could bathe in what seemed to be a light-colored mud. Here also he washed his socks and his shirts.

[1] Abstract from advance sheet, British Medical Journal.

We came up to Frere — I, and my two nurses — with No. 4 Stationary Field Hospital. We reached the camp on the Monday before the battle, when it was reputed that 30,000 men were under canvas. A camp of this size of necessity presented an endless scene of bustle and movement. Nothing seemed to be at rest but the interminable array of white tents and the rows of baggage wagons. Cavalry would be moving in one direction and infantry in another. Here a mounted patrol would be riding out or a couple of scouts coming in. Gallopers would be seen in all directions, and everywhere would be a struggling team of oxen or of mules enveloped in clouds of dust and urged on by sweating men and strange oaths. The camp, during the day, lay dry, dusty, parched and restless under a blazing sun, but at night there was a cool wind and cheery camp fires, and a darkness which blotted out the dusty roads, the dried up river, the dismal piles of stores, and the general picture of a camp in a desert of baked earth. Every night a search light was at work sending despatches to Ladysmith, and almost every morning could be heard the Boer guns thundering over that unhappy place. Tommy Atkins looked very smart in his khaki suit when leaving Waterloo Station, or when embarking at Southampton, but at Frere he showed the effects of wear, and his tunic, his belt, his pouches, his boots and his face had all toned down to one uniform tint of dirt color. He was of the earth earthy. Even his brown face and red neck were well powdered with the common dust, but nothing seemed to have blotted out his cheerfulness and his determinination to make the best of even a camp on the veld.

BEFORE THE BATTLE.

On Wednesday the army began to move forward to Chieveley, and on Thursday the whole camp had nearly vanished and little remained but smouldering fires of camp refuse, the inevitable dust, the inevitable sun and the inevitable Kaffir.

From a kopje some three miles beyond there — the kopje from which the Boers fired upon the ill-fated armored train — the new camp at Chieveley could be seen. The baggage train which followed the army was eight miles in length. This train was made up mainly of wagons drawn by teams of oxen — 18 to each wagon. The last bearer company was well out of sight in the new camp before the last wagons — carrying pontoons — had started. The course of this enormous caravan across the veld was marked by a line of brown dust which gave one the idea that the very road was smoking under this unwonted burden.

From the kopje we could see the firing of the great naval guns and the clouds of dust sent up by the exploding shells, and now and then from the weary road would come an attenuated sound, which was all that reached us of the shrill yells of the nigger drivers, whose dust-dried throats gave out noises like the shrieks of parrots.

On Friday morning No. 4 Stationary Hospital moved hurriedly to Chieveley. To our numbers had been added two Netley sisters, whose skill, devotion and unselfishness were soon taxed to the utmost. On the way up it was evident that the battle was raging. The roar of the big guns was incessant, and rising above their solemn boom was the sharp, irritable crack of the quick-firing ordnance. Our hospital was about three and three-quarters miles from the Naval Hill on

which our big guns were pitched. Close behind the ridge formed by this hill were four field hospitals. The scene presented at this spot was beyond description. The men were coming in as fast as the ambulances and bearers could bring them. Some were dead, some were dying, all were parched with thirst and baked and blistered with heat. The men were lying on all sides on stretchers — amidst tents, piles of rifles, accoutrements, battered helmets and blood-stained tunics. It was a sight no one would wish to see again, and the blazing sun added to the miseries of all.

Some 800 wounded were passed through the field hospitals and dealt with by 16 surgeons. Those who harshly criticise the Army Medical Department should have seen the work done on that memorable Friday on the Naval Hill before Colenso. No work could have been done better. The equipment was good, the arrangements elaborated, and the officers worked on hour after hour without rest or food under the most trying possible conditions. No greater strain could have fallen upon a department and all concerned met the brunt of it valiantly and well. One could not be other than proud of one's profession.

In addition to the ordinary bearer companies, Colonel Gallwey had organized a volunteer ambulance corps of some 2,000 men, disposed in the proportion of 12 men to a stretcher. It was intended that these bearers should convey the more seriously wounded from the field, so that they might be spared the jolting of the ambulance wagons over the somewhat rough ground. Not only did the bearers do this and so save infinite suffering, but all Friday night and Saturday they were carrying the graver cases from the field hospitals to the stationary hospital at Chieveley. So admirably was the stretcher work done that not a single wounded man was left upon the field after dark on Friday.

Our hospital at Chieveley was crammed to its utmost, and very many wounded men had to lie all night in the open. Fortunately the nights on Friday and Saturday were very fine, and there was a bright moon.

The work on Friday and Saturday was the heaviest I have ever experienced, and we all suffered a good deal from thirst. The nurses worked not only all day, but also all night. Some hundreds of wounded soldiers will have reason to remember their devotion that day, and how well they succeeded in rendering a little more tolerable a state of misery which was horrible to contemplate.

After a heavy afternoon on the field I returned to Chieveley Field Hospital in the evening, but had hardly got in when a galloper arrived to ask me to see Lieutenant Roberts, who had just been brought back. I returned at once with a full equipment of instruments, and much regret that that valiant soldier was from the first quite beyond the reach of surgery. In addition to a penetrating wound of the abdomen, his forearm was shattered by a Mauser and his knee wounded by a shell. He was pulseless. I slept outside his tent that night, and saw him up to Chieveley on Saturday morning. He never rallied nor regained a pulse, and died on Saturday at midnight. Before he was brought in he had been lying for seven hours in the sun in a donga. He was attended to by Major Babtie, R.A.M.C., who rode into the donga through a hail of bullets, and whose horse was killed under him. Major Babtie kept by the many wounded men in the donga until the battle was over, and as he alone had water in his water bottle he doled out water to each man in a minim measure, one drachm to each.

On Sunday we had to leave Chieveley as the hospital was within reach of the Boer shells. We therefore retired to our previous "pitch" at Frere. The hospital tents at Chieveley were admirably situated, but the work was much hampered by want of water. The temperature on Friday and Saturday was up to 100° F. in the shade. On Monday the temperature rose to 104° F. in the shade. A clinical thermometer in a bag and under cover of a tent registered 104.5° F.

The method of dealing with the wounded in the Natal Field Force is as follows: The railway — a single line — is open as far as Chieveley, and on it are two admirably-equipped hospital trains in charge of the indefatigable and ever-obliging Major Brazier-Creagh, R.A.M.C. The hospital train was on the field before daybreak on Saturday morning, and was soon filled with wounded. Some few of these were landed at the No. 4 Stationary Field Hospital at Chieveley, the rest were taken on to Estcourt and Maritzburg. At both these towns, but especially at Maritzburg, there is very excellent hospital accommodation. The base hospital alone at Maritzburg can take in 1,100 patients, and, besides, there is the large military hospital at the College, Grey's Hospital, and the hospital for volunteers established at the Legislative Assembly.

From Maritzburg the patients are sent down to Durban by the hospital train, and are then conveyed to Cape Town by the hospital ship *Spartan*. From the careful examination I made of her when I boarded her at Durban, I should think she was the best equipped and best-managed hospital ship afloat.

Colonel Gallwey's organization has now been tested to the utmost, and has been proved to be efficient and admirable. The wounded placed upon the hospital train by the Naval Hill below Chieveley could have — as soon as they were placed in their berths — iced soda water and whiskey, iced milk, hot soup, or even champagne and seltzer.

The great majority of the wounds are by Mauser bullets, some few are due to fragments of shell, and a still less number to shrapnel. The Mauser bullet is a very merciful one, and in no instance have I met with a case in which the head of the bullet had been cut off, as had been asserted by some. The damage done by the Mauser depends mainly upon the range. At 1,500 to 2,000 yards it penetrated like a needle. At 500 yards or less it will smash a femur or a humerus to fragments. When a bone is fractured the bullet — if retained — is generally found to be much distorted or broken up into many fragments. The shell generally peels off the leaden core. As an instance of the fine hitting of the Mauser, I may mention a case (from the armored train) in which the bullet went through the middle phalanges of the ring and little fingers, making four small wounds which healed kindly and neatly. The two bones were fractured, but the man recovered with sound union and mobile joints. On the other hand, I have seen a fracture of the humerus in which the bone was broken into twenty-three small fragments. Many gunshot fractures of the thigh heal by first intention.

The point of entry of the Mauser is very small — often, as Tommy says, like a bugbite; it is not difficult to overlook. The point of exit is also often very small, but is more apt to be slit-like. The hole made

in the bowel by the Mauser is very small, and can be closed by from three to five Lembert sutures. Several penetrating wounds of the liver and kidney have been followed by no symptoms. One distinguished officer had a shrapnel bullet pass through his liver and kidney. He had little collapse, and beyond some temporary tympanites and hematuria he had no trouble of any kind.

In several instances the bullet has passed through the brain without causing marked symptoms, and perfect recovery has followed. For example, a bullet entered near the vertex, passed through the brain, hard palate and buccal cavity and escaped at the root of the neck on the opposite side. No discomfort followed except headache and some strabismus. Speaking generally, operations upon the skull for gunshot wound have done exceptionally well, and such operations have been numerous. I met with four cases of paraplegia on Saturday, the bullet having in each case apparently passed through the cord.

Amputations have been comparatively few. I have seen a Mauser go through the centre of the patella and out at the centre of the popliteal space, and lead to no trouble in the joint. Some cases are hard to understand; as, for example, one in which the bullet entered above the clavicle and came out on the inner side of the opposite thigh, there being no symptom except temporary shock.

The field dressing carried by each soldier answers its purpose admirably.

On all sides there is evidence that our soldiers behaved splendidly on the field; and I can say that when brought back wounded they were plucky, patient and uncomplaining. Their unselfishness was many times very marked.

Obituary.

FRANCIS CHARLES PLUNKETT, M.D.

DR. FRANCIS CHARLES PLUNKETT, whose death occurred November 29, 1899, was born in 1842 at Castlemere House, County Mayo, Ireland. At the age of fifteen years he passed the preliminary examination at the Royal College of Surgeons, Dublin, and graduated from there in 1863. In 1864 he came to America and offered his services in the Civil War and enlisted as assistant surgeon in the One Hundred and Eighty-Third Ohio Volunteers. He passed the examination for assistant surgeon, United States Army, but declined a commission. In 1866 he came to Lowell, where, as one of the local daily papers said, "Dr. Plunkett's life in Lowell was a worthy one." He early set himself to work building up his practice and soon became one of Lowell's foremost physicians.

He is survived by a widow, two daughters and one son, Mr. Harry Plunkett, a medical student.

Correspondence.

THE CASE METHOD OF TEACHING SYSTEMATIC MEDICINE.

PHILADELPHIA, PA., January 28, 1900.

MR. EDITOR: — The principles for which Mr. W. B. Cannon so ably contends in his article on "The Case Method of Teaching Systematic Medicine," have long been recognized, and so far as possible applied in the teaching of clinical surgery at the University of Pennsylvania. I have for years endeavored to make the students acquire for themselves in any given case the facts necessary for a diagnosis, carry out for themselves the reasoning process by which the diagnosis is reached and then defend their opinion and the treatment they recommend against my criticism or that of other teachers.

The usual limitations of clinical material have prevented this course from being as systematic or as comprehensive as I desired, and it had not occurred to me to use the histories of cases in the way suggested by Mr. Cannon. I am writing to express my obligations and to enclose copies of histories which were given yesterday to the students of the third and fourth year classes. I cordially agree with your editorial estimate of the probable usefulness of this plan.

Yours truly,

J. WILLIAM WHITE, M.D.

[The foregoing letter relative to Mr. W. B. Cannon's paper, published in our issue of January 11th, on "The Case Method of Studying Systematic Medicine," leads us to suspect that Dr. White has not clearly in mind the distinction which Mr. Cannon intends to draw between the conference and the case systems. The essential feature of the conference system as practised for many years at the Harvard Medical School is the careful study and report of an actual case by one student, the remainder of the class acting mainly as listeners, rather than as actual participants in the investigation. The advantages of such a method for the individual student are manifest, and, in fact, probably greater than any other as yet devised. For the body of the class, however, who have had no opportunity to see and examine the case under consideration, the discussion loses much of its significance and value. Mr. Cannon's scheme is devised to obviate or supplement this weakness of the conference system by substituting histories of cases which each student in the class may have an equal chance to study, and therefore to discuss with intelligence and interest. The essence of the plan is to throw open to all the students the advantages derived from a personal study of actual cases, rather than limit those advantages to the few. Inasmuch as the study of patients, by a large class, is impracticable for obvious reasons, the alternative of studying case histories presents itself; the demonstration of this possibility is due Mr. Cannon, as outlined in his paper, and in this idea, we are confident, lies an essentially new and very hopeful field for the development of medical teaching. We are glad to know that the plan is being tested in Philadelphia, as it has been, with success, in Boston.—ED.]

METEOROLOGICAL RECORD

Deaths reported 2,438; under five years of age 785; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping-cough, erysipelas, fevers and consumption) 550, acute lung diseases 517, diphtheria and croup 103, measles 41, typhoid fever 35, scarlet fever 26, diarrheal diseases 25, whooping-cough 18, erysipelas 9, cerebrospinal meningitis 9.

From diarrheal diseases New York and Baltimore 8 each, Pittsburg 4, Fall River 2, Washington, Providence and Nashville 1 each. From scarlet fever New York 16, Boston 4, Pittsburg, Worcester, New Bedford, Holyoke and Fitchburg 1 each. From whooping-cough New York 9, Boston, Baltimore, Washington, Providence, Charleston, Lawrence and North Adams 1 each. From erysipelas New York 6, Boston 2, Baltimore 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,236, for the week ending January 20th, the death-rate was 24.9. Deaths reported 5,552: acute diseases of the respiratory organs (London) 728, measles 121, whooping-cough 115, diphtheria 96, fever 39, scarlet fever 35, diarrhea 35, small-pox (Liverpool and Hull 1 each) 2.

The death-rates ranged from 11.2 in Oldham to 32.2 in Nottingham: Birmingham 27.9, Bradford 26.3, Cardiff 14.5, Gateshead 19.5, Hull 27.5, Leeds 20.6, Liverpool 32.0, Manchester 22.2, Newcastle-on-Tyne 25.6, Portsmouth 19.8, Sheffield 26.2, Swansea 18.3.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 3, 1900.

H. E. AMES, surgeon, detached from duty in connection with the "Kearsarge" and ordered to duty on board that vessel February 20th.

J. C. BOYD, medical inspector, commissioned as medical inspector from October 25, 1899.

R. WAGGENER, pharmacist, detached from the "Pensacola" Navy Yard and ordered to be examined at the Washington Navy Yard, February 13th, for retirement, and then home to wait orders.

(CHANGE BY CABLE FROM ASIATIC STATION.)

J. J. SNYDER, assistant surgeon, detached from the "New Orleans" and ordered to the "Isla de Cuba."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING FEBRUARY 1, 1900.

WERTENBAKER, C. P., passed assistant surgeon. To proceed to Winston, N. C., for special temporary duty. January 29, 1900. To proceed to High Point, N. C., for special temporary duty. January 31, 1900.

NYDEGGER, J. A., passed assistant surgeon. To proceed to Manila, P. I., and report to Passed Assistant Surgeon J. C. PERRY for duty. February 1, 1900.

TABB, S. R., assistant surgeon. Granted extension of leave of absence for seven days on account of sickness. January 27, 1900.

GRUBBS, S. B., assistant surgeon. To proceed to Marseilles, France, for temporary duty. January 31, 1900.

KAUFFMANN, H. B., acting assistant surgeon. Granted leave of absence for thirty days on account of sickness, from February 3, 1900. February 1, 1900.

RECENT DEATHS.

AUSTIN MARSH, M.D., M.M.S S., died February 2d, at Carlisle, Mass. He had been a member of the Society since 1839.

A. P. RICHARDSON, M.D., a prominent physician and contributor to the JOURNAL, died at his home in Walpole, N. H., February 3d. He had practised in Walpole for thirty-four years. He was sixty-five years of age, was a graduate of the University of Vermont and was formerly president of the New Hampshire Medical Society.

ERNEST G. METCALFE, M.D., of Brooklyn, N. Y., died February 2d, from Bright's disease, at the age of forty-nine. Dr. Metcalfe was a Civil Service Commissioner from 1886 to 1888, and for four years was an examiner in lunacy for the Department of Charities.

SIR THOMAS GRAINGER STEWART died in Edinburgh, February 3d, at the age of sixty-three. He was educated at the high school and University of Edinburgh, and subsequently studied in the universities and hospitals of Berlin, Prague and Vienna. On his return to Edinburgh he became resident physician in the Royal Infirmary. In 1876 he was appointed professor of the practice of physics at the University of Edinburgh. He was an honorary Fellow of the Royal College of Physicians of Ireland, and of the College of Physicians, Philadelphia, an M.D. of the Royal University and received the like honor from the University of Dublin on the occasion of the tercentenary of Trinity College. From the University of Aberdeen he received the degree of Doctor of Laws. He was at various times president of the Royal College of Physicians and of the Medico-Chirurgical Society of Edinburgh, and of the Section in Medicine of the British Medical Association, and was one of the honorary presidents of the Berlin International Congress. He presided over the meeting of the British Medical Association in August, 1896. In 1892 he was appointed physician in ordinary to the queen in Scotland. He received the honor of knighthood in 1894. He was representative of England at the International Congress on Tuberculosis, which met at Berlin in May of last year, and took an active part in the discussions.

A SYSTEM OF CLINICAL INSTRUCTION.—FOR THE SIMULTANEOUS INSTRUCTION IN SMALL SECTIONS OF A LARGE NUMBER OF STUDENTS.

BY A. H. WENTWORTH, M.D., BOSTON,

Assistant in Diseases of Children in the Harvard Medical School; Assistant Physician to the Children's Hospital; Senior Assistant Physician to the Infants' Hospital.

THE purpose of the paper is to show that large numbers of students can be given clinical instruction in small sections on the same day. A plan for the introduction of this method into the third year course of study in the Harvard Medical School required a few alterations to be made in the present system of instruction for that year, in order to obtain the requisite time. These changes must not be construed into an attempt on my part to revise the course of instruction for the third year. My object is simply to demonstrate the practicability of section teaching.

Some of the faults in the present method of teaching clinical subjects are that the student hears a great deal but does very little himself; that he is not made to think for himself; that he is not made to express and to commit himself before others, and that he is not given opportunities to make mistakes and to have them corrected. He, therefore, fails to learn systematic and accurate methods of examination; his deductions are very faulty and he acquires but little self-reliance.

Not that I would advocate abandoning lectures and large clinics. I believe that they are essential in order to complete the students' knowledge. I would merely give fewer lectures on clinical subjects and make the greater part of the work practical by teaching the students in small sections at the bedside, and in out-patient departments. The present system of making ward visits is only partially successful in this respect, because the sections are too large to enable the students to examine the patients individually. In most cases the instructor calls attention to the abnormalities, and permits as many students as possible to examine very superficially what he has pointed out to them. In some cases one or more students are assigned to a patient while the remaining students are making the rounds with the instructor. These students have an opportunity to think for themselves and to thoroughly examine the patient. The obvious fault here is that only a limited number of students have such opportunities, and in the course of a year's instruction even these fortunate ones have examined but a limited number of patients. The fundamental principle of all instruction should be that all of the students should have *equal* opportunities, otherwise the system is manifestly unfair. A certain amount of section work is laid out for the students by the present system, but each section rarely goes more than six times in the course of the year. This is just enough to show the student how desirable it would be if he could only have more of it.

For several years I have employed the method which I am about to describe in teaching sections consisting of nine students in a section.

Three students are assigned to each patient. They are allowed three-quarters of an hour in which to make their examinations. The histories of the cases are withheld until the instructor goes over the cases. The students are permitted to ask the patients only such questions as relate to the physical examination. The object of this is to prevent the students from forming hasty conclusions about the cases, and thus to force them to make systematic and thorough examinations of the patients.

The students are informed beforehand that all that is required of them is to make accurate physical examinations of the patients with reference to their general condition and the condition of the various organs. If they are able to make diagnoses from the results of their examinations, so much the better. After a little practice they almost always make provisional diagnoses and have prepared a series of intelligent questions about the history and the results of the examination of urine, blood, etc., which will help them to decide. This is a good drill and teaches them careful observation and system.

At the end of the allotted time, the instructor asks them various questions about the normal organs as well as about the abnormal ones, in order to be sure that they have neglected nothing. They are expected after a few exercises to be able to tell the instructor everything that is abnormal about the case without his asking them a question.

When they have finished the description the instructor goes over the case himself and corrects or verifies their observations. The remaining six students are then permitted to examine any abnormalities which may be present.

The discussion of the case is then taken up. Deductions are made from what has been found. The students' diagnoses are criticised. Differential diagnosis is carefully considered. The students are questioned about the diseases which ought to be considered and how some of these diseases can be ruled out. This part of the exercise is of the greatest value, because it not only makes the students think for themselves, but they are forced to express their opinions before the other students. It teaches them to express themselves clearly, and to arrange their confused ideas. The remaining students are appealed to, to suggest anything which has not been considered. In this way, they all take part, and when the "quiz" on one case is completed, the instructor rapidly considers the etiology, symptoms, complications, prognosis and treatment of the disease which has been diagnosticated. There is usually not much time left for this, so that this part of the instruction must be concise and to the point if the instructor hopes to complete the three cases.

The value of this system becomes apparent in a very few exercises. The students become *thinkers;* they become self-reliant; they are obliged to do their own work. They are criticised *freely* and impartially but never ridiculed, and they take pleasure in it because they note the improvement from day to day. It frequently happens that the trained observer's deductions appear so simple and evident that the students are convinced that they had the same thing in mind. It is necessary only to compel them to make the deductions themselves to show them that they erred in supposing they could make these deductions without careful thought and training. They learn more through their mistakes than in any other way.

Two hours is the shortest time, in my opinion, that such a course can be given in. Three-quarters of an

hour for the students and the remainder for the instructor. Even then the time will be found to be very short, because the students require time in which to express themselves, and much time is needed to allow the students to examine abnormalities individually. The students become so interested in examining the cases and in taking part in the discussion that I have not found them to be dissatisfied with the length of the exercise.

The problem in teaching large classes in small sections is to permit each student to examine as many patients as possible in the course of a year. If the sections are small and the class is large there will be fewer opportunities for each student unless the number of instructors is very large. If the sections are too large it will be found that two hours will not suffice for the instructor to go over the cases. If too many men are put upon one case they interfere with each others' examinations in the allotted time of three-quarters of a hour. It has been found by experience that three men on a case get along very well. Two of them can make some of the examination at the same time, and after one or two exercises they keep the run of the time and are careful not to allow one man to monopolize more than his share. Twelve men in a section with three cases cannot be handled so well in two hours, because four men on a case cannot examine thoroughly in three-quarters of an hour. If four cases are given out there is not sufficient time for the students to examine the other cases and for the instructor to discuss them. If two men are assigned to a case in sections of six students it would require more instructors and more patients to enable a large class to be taught at the same time.

In order to obtain the best results the teaching should be uniform. All the instructors should be required to conduct their exercise in the same way. The students should be made to think and to do their own work, and the instructors should correct the students' observations. At first sight this may appear to be a very elementary way in which to teach, and likely to prove objectionable to the instructors on the ground that it hampers their capabilities as teachers by its limitations. I can assure any one who has not tried this method that he will find unlimited opportunities for the display of his talents as a teacher in the discussion of the case and in his subsequent summary of it.

I have chosen 144 for the total number of students, because the classes in the Harvard Medical School have not exceeded that number. But by the method which I am about to describe, the number of sections is limited only by the number of available instructors and by the number of patients which can be utilized. In order to ensure impartial instruction and to avoid dissatisfaction among the students it is essential that a system of rotation should be adopted by means of which the instructors teach each section in turn, so that at the end of a given number of exercises the entire class shall have been taught by each instructor. Furthermore, it is important to give more clinical instruction in some branches of medicine than in others. In my scheme I have assigned 50 per cent. of the clinical instruction to clinical medicine, 25 per cent. to clinical surgery, and the remaining 25 per cent. to pediatrics, clinical pathology and contagious diseases.

In the plan which was submitted to the Committee on Education in the Harvard Medical School, section teaching was arranged for four times a week. This was a provisional arrangement owing to the number of available teachers. It would be an improvement to give section teaching six times a week. The time required for each exercise is two hours, but the hospitals in Boston are some distance apart and it was necessary to allow an additional hour for some of the sections to cross the city (Table I). The hours from 10 A. M. to 1 P. M. were selected for this purpose. The tabular view of the arrangement will make this clear. The sections which have to cross the city will begin their exercise an hour later.

The entire class is divided into sections consisting of nine students in a section. If the number of students does not permit an equal division into sections of nine men, one or two of the sections can consist of six students. The sections are numbered, and the students in each section retain the same numbers throughout the year. The assignment of students to sections can be made a day or two before the beginning of the fall term. The names can be bulletined, and if desirable a day or two can be allowed for some of the students to exchange into other sections.

TABLE I.

TABULAR VIEW FOR THIRD YEAR REVISED TO ALLOW SECTION TEACHING ON FOUR DAYS IN THE WEEK.

Monday.	Tuesday.	Wednesday.	Thursday.	Friday.	Saturday.
9. Clinical Medicine. (M. G. H.)	Clinical Medicine. (B. C. H.)	Clinical Medicine. (M. G. H.)	Theory and Practice. (M. G. H.)	Clinical Surgery. (B. C. H.)	Clinical Medicine. (B. C. H.)
10. Surgery. (M. G. H.)	Clinical Surgery. (B. C. H.)	Section teaching from 10 to 12, or from 11 to 1, for those sections which have to cross the city to other hospitals (see tabular view of section teaching).			
11. Theory and Practice. (M. G. H.)					
11½.	Pediatrics. (Med. School.)				
12. Surgical Conference. (M. G. H.)					
3. Obstetrics. Lecture. (Med. School.)	Theory and Practice. Lecture. (Med. School.)	Obstetrics. Conference. (Med. School.)	Obstetrics. Lecture. (Med. School.)	Theory and Practice. Lecture. (Med. School.)	
4. Surgery. Lecture. (Med. School.)	Obstetrics. Recitation. (Med. School.)	Pediatrics. Lecture or recitation. (Med. School.)	Surgery. Lecture. (Med. School.)		

If it were considered preferable to continue to teach dermatology and neurology in the third year instead of in the fourth year, arrangements could be made for one lecture to be given in each of these subjects every week and for one section to be assigned to an instructor in each of these departments to receive section teaching.

Abbreviations. — B. C. H. = Boston City Hospital; M. G. H. = Massachusetts General Hospital; C. H. = Children's Hospital.

At the end of 16 exercises the rotation is complete and Section No. 1 has returned to its first instructor.

Clinical pathology and pediatrics alternate with each other. During the *first* rotation of 16 exercises the odd numbers are assigned to clinical pathology and the even numbers to pediatrics. During the *second* rotation the odd numbers are assigned to pediatrics and the even numbers to clinical pathology. This must be remembered in preparing a tabular view for the entire year.

By this arrangement each section has two exercises in clinical medicine; one exercise in clinical surgery; one exercise in clinical pathology, *or* pediatrics, *each week*, and one exercise in contagious diseases every *fourth* week.

In an average school year of 32 weeks *each student* will have examined 192 medical cases, 96 surgical cases, and 48 children.

A tabular view of the section work for the ensuing year can be printed at any time before the school year begins and distributed among the students after they have received their section numbers. In this way all confusion will be avoided and the students will present themselves at the various hospitals at the hours assigned, without further notice. The absence of one or more students from a section will not interfere with the instruction of the remaining students.

By adopting a system of rotation each section meets a different instructor each time until the rotation has been completed and Section No. 1 has returned to its first instructor. In arranging such a system it is necessary so to arrange the instruction that at the end of rotation each section shall have had the same number of exercises in each subject. This may be accomplished by arranging the subjects in such a way that the same subject shall not be assigned to more than one section in succession, that is, two sections should not be taught clinical medicine in succession. If this arrangement is not adhered to, it will be found at the end of several exercises that one section will have had more instruction in surgery, and another, more in clinical medicine, etc. A study of Table II will explain this.

To avoid interfering with the rotation and at the same time to give less instruction in clinical pathology and in pediatrics, these two subjects are arranged to alternate with each other. It will be seen that during the *first* rotation the odd numbers are assigned to clinical pathology and the even numbers to pediatrics. To enable the sections that had pediatrics to have clinical pathology and *vice versa*, it is necessary in the *next rotation* to assign the even numbers to clinical pathology and the odd numbers to pediatrics. This alternation must be arranged in the tabular view. After receiving their section numbers at the beginning of the term, the students have only to consult the tabular view to find out which hospital to go to and what the exercise will be on any day in the school year.

There is one important objection to the method of teaching, namely, the number of instructors that are needed. This objection applies chiefly to clinical medicine. If the method were adopted in the Harvard Medical School, *without any alteration* in Table II, it would require eight additional assistants in clinical medicine, because the time of the present instructors is fully occupied in teaching auscultation and percussion. It should be borne in mind that the apportionment of sections can be altered to any extent. Two of the sections assigned to clinical medicine could receive instruction in neurology, a third and fourth section could be assigned to dermatology and to pediatrics respectively. By this arrangement only four additional instructors would be needed in clinical medicine. As a preliminary arrangement for the first year or two, the number of exercises could be reduced to two or three times a week instead of four times.

The purpose of this paper, as I stated at first, is to show the practicability of section teaching, but I should like to add a few words about didactic lectures and to offer a few suggestions about conducting a course in section teaching. I believe that didactic lectures are needed by the students to supplement section teaching. Most of the time at a clinical exercise should be spent in correcting errors in observation and in deduction and in permitting the students to examine the abnormalities which have been detected. The time which remains, if this be done thoroughly, will be found to be so short that the instructor will be forced to omit much useful information about the disease under discussion, information that is often of the greatest value in the management and treatment of cases in practice and much that is essential in order to obtain a clear conception of the nature of the disease. To obtain such information from text-books alone is usually beyond the powers of the student because his reading-time is very limited and because he lacks the experience which is necessary to enable him to separate the essential from the non-essential.

SUGGESTIONS.

(1) The section teaching should be under the control of the professor. This would not require a great expenditure of time if the clerical details were performed for him by an assistant or by a secretary.

(2) A list of the diseases which the professor wished to have shown to the students could be prepared, and the instructors could arrange to show these diseases during the year.

(3) The instructors could keep a record of the diseases which had been shown and the sections that had seen them. These reports could be sent to the professor every week and would enable him to arrange the teaching so that all of the students could see the same diseases in the course of the year.

(4) An effort should be made to show the students different stages and complications of the same disease.

(5) The professor could arrange a series of lectures to supplement the section teaching. These lectures would be delivered before the entire class in the amphitheatre of the hospital and the students would be expected to take careful notes for future study. In a large hospital it would often be possible to find a number of cases in different stages of a given disease. These cases would serve as illustrations and would help to impress a distinct picture of the disease upon the students' minds.

(6) Patients with chronic diseases often remain in a hospital for several weeks. If a given case were shown to each section in turn it would be possible for the entire class to see the same patient in the course of one rotation.

(7) I believe that the students should be required to pass both a practical and a written examination in auscultation and percussion at the end of the second year in order to show that they are competent to begin section work.

THE CASE OF A MAN WHO SWALLOWED HIS SUSPENDERS; REMOVAL BY EXTERNAL ESOPHAGOTOMY; RECOVERY.—OTHER SIMILAR CASES.

BY MAURICE H. RICHARDSON, M.D., BOSTON.

WILLIAM H., shoemaker, aged twenty-nine, entered the Massachusetts General Hospital on April 13, 1899. He had been discharged a few days before from the Worcester Insane Asylum, of which he had been an inmate for thirteen months. He said that two weeks before entrance, while despondent, he attempted to swallow his suspenders. He succeeded in getting down certain portions of the suspenders and some broken glass, but just how much was uncertain.

I questioned the patient repeatedly, but could get little information as to what or how much he had succeeded in getting by the fauces. He was not unwilling to tell, but he was dazed and stupid and somewhat silly. He complained of no pain, but rather of a discomfort under the sternum while eating. The food at times passed easily into the stomach; at times it was immediately regurgitated. There had been no blood in the regurgitated material.

The history given by this mentally unbalanced patient would seem extraordinary, except that the insane do the most incredible things. I had had some experience with foreign bodies in the melancholy and suicidal, and in every case operation had demonstrated the truthfulness of the patient's statements, even when it was hard to believe them. I therefore was inclined to accept as a fact that somewhere in the alimentary tract would be found portions, at least, of the man's suspenders, and perhaps other things. The precordial discomfort and the occasional regurgitation suggested impaction in the esophagus. The man was physically strong and well developed; mentally, he was slow and stupid. Nothing could be seen or felt in the fauces. With the olive-tipped probang an obstruction of some kind was perceptible in the esophagus at or about the level of the transverse portion of the aortic arch. Nothing metallic could be detected. An x-ray negative showed unmistakably a suspender buckle at the level of the arch, and possibly another higher up.

The safest route of removal — whether by mouth, by external esophagotomy, or by gastrotomy — was the most important question in this case. The chief danger in esophageal impaction is from ulceration into the great vessels, especially when the impacted body is a flattened one with sharp edges — a coin, a tooth plate, for example. Moreover, the usual time for a fatal erosion is two weeks or less. In this case, therefore, the erosion, if any was taking place, must have been sufficiently advanced to make even the most refined manipulations dangerous. Indeed, it would be by no means surprising if attempts at extraction, by whatever route, would end in a deluge of blood from the aorta. The selection of route would depend, not upon the facility with which a hemorrhage might be checked — for such a hemorrhage could not, of course, be checked — but rather upon the feasibility of detachment and removal without causing that hemorrhage.

The instruments usually selected for removing foreign bodies from the esophagus through the mouth cannot with intelligence be either directed, applied to the foreign body, or withdrawn. Some of them, once fast to a foreign body, cannot be made to let go. Some years ago the coin catcher got fast to a tooth plate impacted at the lower end of the esophagus, and in attempts to detach it enough force was applied to it to break off the metal end of the coin catcher. No harm was done in this case, but it is easy to imagine what might have happened — what, in fact, often has happened in trying to dislodge foreign bodies. On the other hand, I removed with great ease, by means of a coin catcher, a tooth plate which had been for eleven months impacted in the esophagus behind the sternoclavicular joint. I had fully decided to operate through the neck and was using the coin catcher to determine the firmness of the impaction, when the plate became detached and was drawn up.

In the present case the impaction was considerably above the aortic arch. Though we could not make out exactly the kind of buckle, it was evidently a flattened metallic thing, with sharp edges, and it was caught in most dangerous proximity to the aorta and its great branches.

From these considerations I decided to take no chances by instrumentation through the mouth. Gastrotomy was not seriously considered, because the foreign bodies were high up. By external esophagotomy the esophagus could be inspected, felt of, the foreign bodies could be accurately localized, instruments could be directed, applied and withdrawn with precision.

External esophagotomy was performed April 15th. As soon as the esophagus was opened, a thin, brownish, foul-smelling fluid escaped. The finger detected at once that the esophagus below the incision was plugged with something soft. By means of curved, long-bladed hemostatic forceps there were first removed a ball and string attached to a brass ring; then half a suspender web with two buckles; then a third buckle — all covered with a dark, foul-smelling slime. The olive probang, the coin catcher, the bristle probang were successively passed into the stomach without meeting further obstruction. With the finger an ulcerated area could be felt just above the aortic arch. The esophageal wound was closed in two layers with fine, interrupted silk sutures. The external wound was closed except for a gauze strand, leading from the esophageal sutures.

The wisdom of provisional gauze wicking was shown, I think, by this case, for at the end of twenty-four hours there was a fully-developed wound infection, with a temperature of 104°. Thorough irrigation of the wound was followed by rapid subsidence of the infection, the wound rapidly healed, deglutition became normal. The patient was discharged on the 29th of April, physically well, but mentally as unsound as ever. Seven months later, I received the report that the patient was very well, both physically and mentally; that there was no trouble in deglutition and that the wound was in good condition.

The things that an unbalanced patient may do are certainly extraordinary. That he may do them should be borne in mind in obscure symptoms connected with the alimentary tract. My experience has not been large, but it has been enough to guide me to the lesion in several curious cases, some of which I have already published in detail.

One of the most extraordinary was that of a strong young woman who swallowed successfully a gold pencil. She then got an open safety pin stuck in her gullet and detached it with a steel crochet needle, which she then successfully swallowed. This was followed by a lot of common pins. For gastric symptoms, I opened the pylorus, through which I found sticking the open safety pin. I left the other articles in the alimentary canal, whence in due time they all emerged, except the crochet needle, which never has been found.

My first dissecting-room subject had her stomach full of straw. The specimen is now in the Warren Museum. Recently, Dr. Brewster removed for me a ball of hair from the small intestine of a girl of ten years old. This hair ball had completely obstructed the lumen.

An insane woman, after her cup of tea, swallowed the sharp-edged silver teaspoon. It lodged in the

esophagus bowl downward. I succeeded in removing it by external esophagotomy, without hemorrhage. She died, however, in a few days from some unknown cause. There was no wound infection to account for her death.

In another case, that of a hysterical girl, I opened the epigastrium for a tumor supposed to have been caused by the habitual swallowing of rubber gum. Though no gum was found, there was an abscess about the pylorus which I have always thought was caused by the gum. This girl recovered.

Perhaps a little remote, anatomically at least, are the cases of foreign bodies introduced into the rectum. They illustrate, however, the freaks of the insane, the hysterical and the perverted. The most extraordinary instance I have known was the man who lost a ketchup bottle in his rectum, whence Dr. Warren successfully removed it.

Dr. Warren's case recalls that of a general paralytic, in close confinement, whose silver-plated dinner knife disappeared. It was a brilliant exemplification of the possibilities of eliminative diagnosis, for a careful search eliminated every possible place of concealment except his rectum, where, in fact, he had concealed it. He had thrust the knife through the rectal wall into the abdominal cavity, where it was lying free when I explored. A general peritonitis was under full headway, and he died.

Another case deserves mention, though it is not quite analogous to those described. A hysterical and neurasthenic woman declared that she had accidentally swallowed a plum stone, and suffered, she said, extreme torture from its pressure in the stomach. A surgeon, thinking (as I believe rightly) that her troubles were imaginary, passed an instrument into the stomach, withdrew it and showed the patient a plum stone. Unfortunately, the patient immediately declared that it was not that kind of a plum! I finally opened the stomach in this case, but found nothing. The woman died later from an acute inflammation of the alimentary tract caused by drinking, with suicidal intent, corrosive-sublimate solution.

THE CLINICAL VALUE OF OLIVER'S HEMOCYTOMETER. [1]

BY DAVID D. SCANNELL, A.B., HARVARD MEDICAL SCHOOL, BOSTON.

DURING the course of a series of lectures on the physiology of the blood delivered before the Royal College of Physicians, of London, in 1896, George Oliver, an English physiologist, described a new and ingenious method of red corpuscle estimation, at once time-saving and accurate as compared with the Thoma-Zeiss procedure. The invention of this new device was prompted by the same desire for physiological exactness and investigation that led to the production of his tintometric hemoglobinometer, the observations of which are fully as accurate, reliable and definite as the hemoglobinometers of von Fleischl and Gowers.

In his argument for the need of an apparatus more exact and consistent than the Thoma-Zeiss counter, Oliver says: "The present methods for determining the red corpuscles are, (1) the examination by the microscope, and (2) the percentage estimation by the centrifugal machine. The former enumerative method is perhaps on some grounds preferable, especially for clinical work, for it enables any alterations in the individual corpuscles to be observed at the same time. But repeated observations have shown that this same method as ordinarily applied does not possess that degree of accuracy with which it is usually credited. Even though all the necessary precautions have been taken, a series of trials derived from the same mixture of a sample of blood may yield the wide variation of *ten per cent.* The possibility of such a large margin of difference must render the method totally unreliable for any physiological inquiry, however immaterial it may be for clinical purposes. Extended enumeration will, of course, average the discrepancies, but it necessarily involves the expenditure of more time, labor and eyesight than are at the disposal of most observers, especially, too, as physiological work demands the largest possible collection of data and much repetition. It was therefore necessary to search for a simple and time-saving method of hemocytometric observation which, founded on extended enumeration in the first instance and attaining to the accuracy of it, might be substituted for it."

Oliver's hemocytometer is based on the following principle: In the process of drawing out a glass tube, the sides of the tube become minutely corrugated in the direction of its axis. When a candle or small gas flame is looked at through this tube containing water, a transverse line of light is seen, consisting of closely packed minute images of the flame produced by the above-mentioned corrugations of the glass. The parallel furrows and ridges are demonstrable with the aid of a small magnifying glass. Each ridge acts as a lens, hence the horizontal line made up of an aggregation of the images of the flame.

Oliver discovered that if, instead of the water as a refracting medium, he used normal blood diluted with some fixing fluid (such as Hayem's, ferrocyanide of potash, or sodium chloride), the resulting mixture presented a degree of opacity varying according to the amount that the blood was diluted by the fixing fluid.

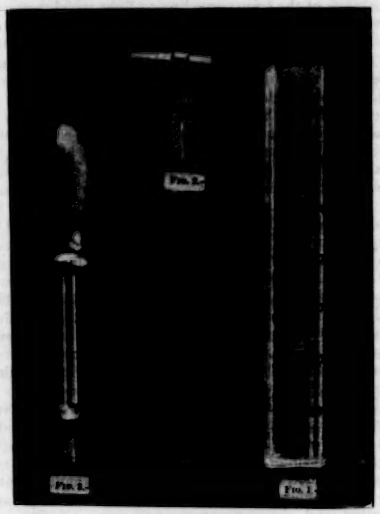
The opacity so produced completely shuts off all view of the transverse line of light until, on still further diluting, a definite point is attained when it can be seen faintly as a delicate thread of light running transversely across the tube, "the dawn, as it were, of the bright minute images of the flame seen when the opacity is absent or still further reduced." Repeated observations by Oliver have shown that the development of this delicate horizontal line by dilution of the blood with either of the fixing fluids mentioned is an extremely sensitive index of the number of red corpuscles present in any individual blood. This was determined in many ways; for example, by the observation that the amount of fixing fluid required to bring the horizontal line into view was always in proportion to the different quantities of the same blood experimented with, and therefore in proportion to the number of the blood corpuscles present at each observation.

The apparatus required for such observation is extremely simple and should be relatively inexpensive. It consists of (1) a flattened graduated tube; (2) a capillary pipette having a capacity of 10 cubic millimetres of blood; (3) a mixing pipette for which an ordinary medicine dropper is a perfect substitute; (4) a candle or gas flame, and (5) a fixing solution, preferably Hayem's.

[1] From Dr. Richard C. Cabot's clinic at the Massachusetts General Hospital.

(1) A flattened tube was adopted because it was found that a round one of such a diameter as to furnish the required degree of opacity would only provide a sufficiently wide scale when a much larger quantity of blood was taken than was commonly used for blood observations; whereas, when the observation was made through the long diameter of a flattened tube, it was unnecessary to use more than 10 cubic millimetres of blood, and the scale is lengthened in proportion to the reduction of the lateral area. A tube of 15 millimetres in the long diameter and five millimetres in the short diameter was found to produce a satisfactory workable scale of 12 centimetres for the determination of 125 per cent. of red corpuscles. The divisions of the scale represent two per cent. and they are sufficiently apart to allow the eye to read one per cent. and even less (Fig. 1).[2]

The determination of the scale was made by the enumerative method applied to 120 squares applied to



the blood of normal man. One hundred per cent. represents the generally accepted standard of 5,000,000 corpuscles per cubic millimetre, and each degree is, therefore, the equivalent of 50,000 corpuscles: 100 per cent. = 5,000,000 corpuscles; 95 per cent. = 4,750,000; 90 per cent. = 4,500,000; 80 per cent. = 4,000,000; 50 per cent. = 2,500,000, etc.

(2) The amount of blood required is measured by a capillary pipette, or automatic blood measurer, having a capacity of 10 cubic millimetres. The end which is presented to the drop of blood is well pointed and polished, so that all traces of blood may be easily removed. The lumen is large enough to permit the passage of a good-sized needle threaded with darning cotton, and is therefore readily cleaned and dried (Fig. 2).

(3) The mixing pipette, or ordinary medicine dropper, is provided with a rubber nozzle which fits over the blunt polished end of the capillary pipette (Fig. 3).

(4) A small-sized wax candle, as, for instance, a Christmas candle, is preferable, since it furnishes a more definite and delicate line than is obtained from a large, coarse flame. However, a reduced gas flame answers perfectly well.

(5) While any of the fixing fluids mentioned above are good, yet Hayem's solution was selected as the most satisfactory for these reasons: (*a*) It is cleanly to use; (*b*) the corpuscles are less affected by it than by any of the other fixing agents, and may be examined microscopically after the observation has been made without fear of material changes, and (*c*) the reading undergoes no variation even after the lapse of many hours (for example, twelve), so that the blood may be washed into the tube and the observations made later if convenient. The constituents of this solution are:

Hydrarg. chlorid. corrosiv.	.5 gramme
Sod. chlor.	1.0 "
Sod. sulph.	5.0 "
Aq. dest.	200 c. c.

Oliver anticipates an objection by stating that it may be suspected that the mercuric chloride present in Hayem's solution may precipitate the proteids of the plasma and thus cause a variable addition to the opacity produced by the corpuscles. This point has been carefully tested, however, with the result that it does not present a source of error.

Apart from the leukemic condition, the white corpuscles do not affect the readings, according to Oliver. The proportion of one white to 500 reds, or one-fifth per cent., is equivalent only to one-tenth of one of the smallest divisions on the scale, and this is unreadable. So that even were the whites to increase up to one in 250, the rise would not appreciably affect the reading of the red corpuscles.

For clinical work I find this method not only simple and accurate, but also eye-saving and rapid. The whole process from beginning to end can, after a little experience, be completed in from five to ten minutes, certainly a saving of time compared with the twenty-five or thirty minutes usually expended by most observers in the preparation and count when the Thoma-Zeiss apparatus is used. Furthermore, it reduces to a minimum the personal equation in the numerical estimation of the red corpuscles, a factor which, with the Thoma-Zeiss counter, is constantly present and indeterminate.

In some cases, of course, it is important to ascertain the size and appearance of the red corpuscles, and therefore the microscopical examination of the fluid is sometimes a useful addendum in cases where changes in these respects might be looked for. As stated before, the nature of the fixing fluid renders this microscopical observation perfectly possible and accurate even after the lapse of many hours.

Technique.— This is extremely simple, and for its success depends mainly on speed. The capillary pipette is first thoroughly cleaned and dried (unless previously so) by the passage of the threaded needle. The mixing pipette, with the small rubber nozzle attached, is next filled up with Hayem's solution and placed conveniently. The ear is then punctured, as for the ordinary blood count, and "milked" gently until a fairly large drop is pendant. The size of this drop is about that required for a white count. The polished pointed end of the capillary pipette is applied

[2] Photographs taken by Mr. Percy E. Brown.

to the drop, which immediately fills the lumen of the tube by capillary attraction. At this point success or failure is dependent upon the degree of speed employed. The pointed end of the pipette is thoroughly and quickly wiped clean of blood with the fingers, the rubber nozzle of the medicine dropper is fitted over the blunt end of the pipette (most satisfactorily with both held horizontally, to prevent premature ejection of the blood by the weight of the mixing fluid), and the 10 cubic millimetres of blood are thoroughly washed into the flattened tube by the compression of the bulb of the dropper. Experience has demonstrated that the quickest and best results are attained when the patient himself holds the flattened tube in a position convenient for the operator. The filling of the pipette with blood, the application of the rubber nozzle of the drop glass to the blunt end of the automatic

blood measurer, and the washing of the blood into the tube, can all be done after a few trials in ten to fifteen seconds. If these steps in the technique are not done quickly, coagulation of the blood in the pipette is almost inevitable, necessitating a cleansing of the pipette and a fresh start. After the capillary pipette has been emptied of its contents, it is best to detach it from the drop glass and make the further additions of the fixing fluid from the latter. The amount of fixing fluid to be used in the subsequent steps will be roughly suggested by the degree of capacity of the mixture already in the flattened tube, or by the previously made hemoglobin estimation, though the latter bears no fixed relation to the final reading.

After the initial addition of Hayem's solution, the contents of the tube are thoroughly mixed by inverting the tube a few times with the thumb over its mouth, care being taken each time on removing the thumb to draw it over the lip of the tube so as to restore as much as possible the adherent fluid. This procedure is repeated after each addition of the solution. The tube and its contents should never be violently inverted or shaken, since such maneuvres readily produce a frothy condition which renders the reading unsatisfactory and erroneous.

The observation is made in a dark room (the darker the better), free from cross-lights. The small lighted candle is placed about on a level with the observer's eyes and 10 feet distant from him. This distance has been found experimentally by Oliver to give the most accurate readings. In making the observation, it is important to exclude as much as possible the diffuse light of the candle. This is easily and satisfactorily done by resting the lower end of the tube with its *long diameter* in line with the candle, in the concavity between the thumb and index finger (Fig. 4), and then holding the tube close to the eye.

The observer must be on the alert for the first appearance of the transverse line of light which progressive dilution brings into view. The earliest indications of the approach of this will be obtained on the sides of the tube when the latter is turned on its axis by the slightest rotation of the hand. The fluid is then added drop by drop until the line is just apparent all the way across the field when the long diameter is in line with the flame. The transition between the total absence of the line and its sudden presence is usually rather rapid. The appearance of the incomplete line on the sides, however, is a constant forerunner of the complete tranverse line and should put one on one's guard. The sign is extremely delicate and it requires at the beginning very careful observation to recognize it without overstepping the necessary dilution which obviously brings it more definitely and unmistakably into view. The first difficulty is the only one, for when the earliest appearance of the line has been once noted, it cannot fail to be afterwards recognized. Furthermore, there is no occasion for hurry in these later steps, for the opacity remains uniform for many minutes.

During the summer of 1899 the clinical observations appended below were made in the male medical Out-Patient Department of the Massachusetts General Hospital. In 27 cases, of which 10 were essentially blood diseases, the blood was examined both by the enumerative method of the Thoma-Zeiss apparatus and the percentage estimation of Oliver's hemocytometer. In this way the results of the former controlled those of the latter. In each case the Thoma-Zeiss count was applied to 10 large or 360 small squares at least, always two and often three drops of the mixed blood being taken. The hemocytometric observations were made twice in many cases, in order to test the consistency of the readings. A white count was also made in such cases as promised either a leucocythemic condition or a high leucocytosis.

From the following table it will be seen that the results, taken as a whole, are strikingly similar. The maximum difference in the two methods of estimation was 108,400, and this occurred in a case of splenic myelogenous leukemia where the whites numbered 480,000. As stated before, the leucocythemic condition is acknowledged to be a source of interference in the reading of the hemocytometer, giving a result less accurate than in non-leucocythemic states; and

yet, even in the presence of so many white corpuscles (a proportion of one white to five reds), the error of 108,000 in the reds as compared to the Thoma-Zeiss count, is not of very serious moment, such a difference not being of the rarest occurrence in the counts of two average observers on the same blood. In the other case of leukemia, lymphatic in character, where the whites were present to the extent of 102,400, the hemocytometric reading showed a disagreement of only 76,000. In cases with no pathological increase of the leucocytes the greatest difference in the results was 74,000, the smallest 4,000 and the average about 35,000. Even granting that the Thoma-Zeiss count was absolutely correct in each instance, this average discrepancy of 35,000 on the part of the hemocytometer would only imply an error of considerably less than one per cent. in the enumeration of 5,000,000 red corpuscles, and certainly this is so small as to be of no significance. In many cases, as stated before, the hemocytometric observations were made twice within a very short interval and in every instance the two readings were identical, a consistency not expected and rarely found in enumeration by the Thoma-Zeiss method.

No.	Diagnosis.	Thoma-Zeiss Red Count.	Hemocytometer Reading = Red Corpuscles.		Remarks.

DIFFUSE PERITONITIS FROM ACUTE APPENDICITIS IN A GIRL AGED THIRTEEN YEARS; OPERATION; RECOVERY.

BY J. COPLIN STINSON, M.D., C.M., SAN FRANCISCO, CAL.

J. R., age thirteen, a thin, nervous child, although never sickly, was seen by Dr. D. A. Beattie, of Santa Clara, July 13, 1899. She had been acutely ill for thirty hours, complained of severe pain over the right side and tenderness over the whole abdomen, temperature 103½°, pulse 128. On his second visit at 3 P. M., temperature was 103, pulse 122. Ice bags were continuously applied and small doses of the mild chloride and salol given. At 6 P. M. Dr. J. U. Hall, of San Jose, was called in consultation and confirmed the diagnosis of appendicitis made by Dr. Beattie. At 12 o'clock midnight the pain was less on account of opiates, but the area of pain had extended. Temperature 102½°, pulse 112. The pain caused so much rigidity and spasm of the abdominal muscles that now a thorough examination could not be made. I saw the patient with Drs. Beattie and Hall at 8 A. M.

At 9 A. M. I made operation, assisted by Dr. Beattie. Ether was administered by Dr. Hall. An incision an inch long was made over the normal site of the appendix and in a line which followed the trend of the fibres of the external oblique aponeurosis. The subjacent muscles were separated in the direction of their fibres and the peritoneum opened. Pus at once escaped freely. The index finger of right hand was introduced, but no adhesions could be detected. The incision was enlarged and now measured about two and one-half inches. The pus was sponged and washed away and the abdominal cavity further examined. A large mass of inflamed, thickened omentum covered with pus was brought to the surface.

The appendix was gangrenous, bound down by fresh adhesions, contained two large concretions, but there was no perforation; the cecum was inflamed and sloughy. All intestines in sight were inflamed and covered with fibrin and pus. Pus escaped from the pelvis, the left and right sides of the abdomen. All pathological intestines, till normal bowels were freely seen and handled, were withdrawn from the abdominal cavity to the surface and covered with hot towels. The infected portions of the abdominal and pelvic cavities were freely irrigated with water, hot as the hands could bear, and all shreds and fibrin, etc., removed from the peritoneal cavity.

The pathologic omentum was excised. The omentum was spread out, the vessels in it were tied with fixation ligatures of fine chromicized catgut and the omentum cut off external to the tied vessels. No mass ligatures were used. The mesentery of the appendix was separated by dissection well down to the cecum, a bleeding vessel was clamped and ligated with fine chromic catgut, after which the cut edges of the mesentery were approximated with continuous catgut sutures.

The appendix was held up by the tip, and after dividing in a circle its peritoneal and muscular coats about one-quarter of an inch from the appendico-cecal junction, leaving the lymphoid and mucous coats uncut, the divided layers were dissected back to the cecum and a narrow-bladed lock forceps was applied transversely to the lymphomucus cylinder, close to the cecum to temporarily close its canal. The appendix was cut off close to the forceps, leaving only a small cuff of mucus membrane, etc., protruding beyond the outer edge of the forceps. The cuff was cleansed with moist gauze and the cut edges of the mucous and lymphoid coats were united with a single layer of continuous fine chromic catgut stitches, after which the forceps were removed. Several continuous sutures were also used to approximate the peritoneal and muscular coats, but the latter stitches did not hold as the layers were very soft. All pathologic and exposed intestines were freely irrigated with hot water; all visible pus, shreds, plastic fibrin, fibrinous exudate, etc., on the surface of the bowels, etc., were removed with the fingers and gauze pads. The infected portion of abdominal cavity, intestines, etc., were again thoroughly flushed with hot water till the fluid came away clear, dried with sponges and the intestines returned within the abdomen to as near as possible their normal positions.

The peritonitis was a spreading or diffuse infection without the formation of protective adhesions and (as near as could be estimated during a very hurried and critical operation) involved the appendix, the cecum, the lower one-half of the ascending colon, over seven feet of the ileum, the adjacent omentum and the parietal peritoneum extending from the infected viscera.

The inflamed, sloughy surface of the cecum, the line of sutures at the former site of appendix and the adjacent parietal peritoneum were lightly covered with aristol. The upper angle of the wound was closed with several medium-sized continuous chromicized catgut sutures. No more suturing was done, as the patient was in a weak condition and I did not wish to further prolong the operation.

The balance of the wound was consequently left open and lightly packed with borated gauze strips each two inches wide. A strip was carried down to the posterior abdominal wall between the ascending colon and the lateral wall; a second between the cecum and the lateral wall, a third between the inner surface of colon and other adjacent coils, a fourth between the inner surface of cecum and adjacent viscera, and a fifth under the inner portion of abdominal wound for about three inches between the parietal peritoneum and intestines. The surface of the cecum was lightly covered and the wound lightly packed with gauze, and the dressings, adhesive strips and binder applied. She was put to bed in rather weak condition but shock was combated successfully. I saw her twice after the operation. The post-operative treatment was carried on by Dr. Beattie.

On July 8, 1899, some gas with foul odor escaped from wound, but no fecal matter was ever noticed. The wound healed kindly and was solidly cicatrized by August 25, 1899. She was allowed up September 8, 1899. Her general condition is good. She feels well and looks strong. Her appetite and digestion are good. She has no pains in the abdomen; the scar is two and five-eighths inches long, and no hernia has as yet developed.

Reports of Societies.

BOSTON MEDICO-PSYCHOLOGICAL SOCIETY.

J. W. COURTNEY, M.D., SECRETARY.

REGULAR meeting at the University Club, Thursday, October 19, 1899, DR. R. T. EDES in the chair.

REPORT OF A FEW CASES OF INSANITY TREATED BY THE COLD PACK.

DR. ABBOTT read a paper with the above title, chiefly with the view of calling attention to the marked social improvement (so called because of the patient's improvement in his social relations with those about him) which followed the occasional use, or the continuous use for short periods of time, of the cold wet pack in cases so excited, violent or otherwise difficult to manage, that they would have needed seclusion or restraint by nurses or the camisole.

Brief details were reported of a number of cases, including one of epilepsy, with irregularly recurring attacks of irritability increasing to well-marked epileptic furor, four of maniacal phase of manic-depressive insanity, two of mental deficiency with periods of uncontrollable irritability culminating in violent fits of anger, and seven of dementia precox whose conduct for different reasons made them difficult to manage, one being desperately suicidal, another destructive of walls and floors, others making violent attacks on patients or nurses, etc.

That the packs did not act as a means of punishment was shown by the fact that three patients frequently asked for them, many liked them, others were, at most, indifferent to them, and only two resisted them after having had two or three, and of these, one often expressed after them a feeling of great improvement. In every instance an occasional pack or two, or a series of daily packs for a week or two, was sufficient to enable the patient to have the liberty of the ward without special watching. No special therapeutic effect on the psychosis was observed except in the cases of manic-depressive insanity, and in one case of general paralysis, on whom it was tried for that effect alone; in those who had packs regularly for ten days or more there was marked improvement in nutrition. Many slept in the first pack and began to sleep better from that time.

The technique used was practically that described in Baruch's "Hydrotherapy," and it was found that if the very desirable results were to be obtained, four precautions must be very carefully observed: (1) Skin surfaces must be kept separated by wet sheet; (2) the blankets must be kept closely drawn around the neck to exclude the air; (3) the head must be kept constantly cool by means of frequently renewed wet cloths wrapped about it; and (4) the least possible time must be used in getting the patient into the pack. The water in which the sheets were wet was 80° F. for a first pack, about 70° for the second and 60° for subsequent ones. Menstruation was not considered a contraindication; the water was raised to 70° for two days, then lowered to its previous temperature. Patients were kept in the pack for one to three hours, occasionally even longer. In 25 cases treated no harmful results and no disturbing symptoms occurred. The cases were too few in number and the packs given for too short a time to warrant any conclusions as to their therapeutic value in the psychoses.

Dr. Page: I have been very much interested both in the paper and in this subject of hydrotherapy for some years. I would say first that it was never my intention to use it as a form of restraint or for purposes of discipline. I have always had in mind the beneficial and remedial effects of the pack whenever I have used it, and in order that it might not seem to be quite so closely resembling a form of restraint, at one time I secured a quantity of sweaters which were used, dipped those in cold water and applied them so that patients would get all the benefits of keeping the arms away from the surface of the body and not feel quite so constrained as in the ordinary pack. Of course they were wrapped with woolen blankets on the outside, but that would be a less objectionable form or appearance of restraint than a wet sheet wrapped tightly about the person. A record was kept of a good many cases at Danvers. Perhaps Dr. Worcester can give some details of those. I have not had access to the records for a long time and have not made an effort to refresh my mind in regard to them. Packs were used there, but not full packs as a rule — very few instances where the full pack was used. Partial packs were used, especially for insomnia. They used to have a practice of putting on wet bandages or packs, perhaps, to the lower extremities at bedtime. In all such instances a wet sheet was covered by one or two thicknesses of coarse woollen cloth, blankets, or something of that sort, and I think, almost always some waterproof material above that, and the patients were put to bed. Occasionally, instead of applying the packs or bandages to the lower extremities, I have had them applied to the arms, and in some instances it operated, I thought, as well, perhaps better, than where applied to the lower extremities. A few years ago, by the use of wet packs, the use of hypnotic drugs at the Danvers Hospital was almost entirely suspended. There were very few cases where any medicine was given for hypnotic purposes for months. I do not know how it is now, but I think very little hypnotic medicine is used there.

The effect that you want to produce of course should be considered, and your application should vary with the point you have in view, because water is a very powerful agent, and the effect produced by it depends very much upon the method by which you apply it. It seems Dr. Abbott has applied it practically by only one method. If you want to affect patients such as these reported by him, no doubt that was a proper expedient, but for strictly tonic effect I should not think it would be best to continue the pack so long as they were in his cases. A short pack is generally quite as good. Then, too, the water when used under pressure impinges upon the body as in the douche and has a mechanical effect, something of course like massage, and the length of time, variation of temperature and variation of pressure all have certain effects upon the system, and it is important, of course, to understand the physiology of the circulation, especially of the skin, effects of cold, etc., and to know just what you want to do in the case, because there are some principles that seem at first sight almost contradictory which are brought into the field of experimentation, and yet they are not contradictory; they all operate upon plain physiological principles. The fact that water is so very useful and can be used as a domestic remedy is evident from the fact that such a large number of European people, peasants especially, have used the Kneipp treatment for years. Some 200,000 or 300,000 volumes of Kneipp's water cure have been published and sold, and that is certainly proof that it is a popular remedy. I presume most of you remember Dr. Godding thought he had cured two or three cases of general paresis by water treatment. I do not know what the ultimate results were; he never gave a final account of those cases. I never expected to hear he had actually cured them, although he relieved them of some of the disagreeable symptoms, no doubt. I remember being told at the Sunnyside Sanitarium in Southport, England, that they cured there a young man who had been at the celebrated Hallowell Private Insane Asylum in England, and there, by Dr. Phillips, the superintendent, had been pronounced incurable; the friends had been told the young man was hopelessly insane. He was taken to this place and in about six months was restored, and no treatment given except the water treatment. In that case they brought about what the water-cure people have always advocated in certain cases where there was some poisoned condition of the blood; brought about what they called the "crisis," used the water almost continuously on certain portions of the body, kept wet packs on nearly all the time, if not all the time, until a series or crop of foul ulcers were developed, and those were then treated, but they said it would be impossible to heal up such ulcers under several months. The discharge would be peculiarly offensive and disagreeable, but they were never willing to say a case was incurable unless they had failed to benefit them by that method of treatment at that place, and the man who had charge of that was for years associated with the celebrated Harper, I think it was, who was the leading water-cure disciple of England, having a place at Mattock Baths.

I certainly have had great faith and great expectations in regard to what water will do. At Middletown we have not the facilities to carry out the treatment there as I did at Danvers, but I have been preparing plans and a place for the establishing of a hydropathic department, and eventually I certainly expect to have one in full operation. I would say while we do not use the packs there we do not use restraint. We have 2,000 patients, and not one has been under restraint for months.

Dr. Worcester: I don't know that I can add very much to what Dr. Page has said. Although I have from time to time been called in in the absence of other physicians, I have not had patients under my charge for any great length of time. Quite a number of cases during the time in which I have had charge of them have been taking hydrotherapeutic measures in one form or another, and with more or less varying success. I can recall two or three instances somewhat the character of those of which Dr. Abbott has spoken in which it was applied quite persistently without any very marked improvement; in fact I do not recall any case of that character in which the improvement was very decided as far as the troublesome, destructive or violent symptoms were concerned. There has been in a number of cases improvement in the general health and in the nutrition, and I can recall one case of what we classified as acute confusional insanity, although we were very doubtful about the case at the onset and at one time were quite confident she was going to pass into dementia, in which there was coincidently with the use of the packs very marked

improvement and the patient ultimately recovered and went away. I certainly think that the use of hydrotherapeutic measures in that form as well as in others is of very marked advantage in proper cases. I don't feel yet as if I had determined to my own satisfaction the cases in which it would be useful. I have met with very decided disappointment in some cases in which I had pretty confident expectation of benefit.

DR. NOYES: At the Boston Insane Hospital we have no facilities at present for hydrotherapy. Our efforts are directed mainly to the use of the bath tub. I have not tried the wet pack, but of course it is possible to get considerable range of therapeutic use with the bath tub warm baths. Beyond that we have not gone at all.

DR. PUTNAM: I have used the wet packs very largely in cases of debility and anemia and depressed nervous conditions, although not in these cases of pronounced mental disease, and I have been much interested in hearing what Dr. Abbott has said. I think that for getting the best effects as regards improvement in nutrition the wet packs should be followed by colder applications. It seems to me without that the bath as a whole lacks a decided element in its efficiency. The wrapping in the wet sheets and blanket is really to be considered, generally, as preparatory to cold applications, which are relied on to induce tonic contractions of the blood-vessels of the surface and interior of the body and to stimulate the processes of metabolism.

As regards the effect to be expected on the *morale* of the patient, I cannot help thinking the effect of the baths is a good deal like static electricity and any other agent of the sort, a means by which the physician carries one step further the influence of his authority and personal feeling. If he feels confidence in the value of the application or at any rate is able to assume a confidence and inspire the patient, and can make the bath point in that direction it seems to me the results are likely to be considerable. Simply regarded in and for itself I should not suppose on general principles that the baths would have very great effect in that way, and I should not imagine that they would have the effect which Dr. Abbott suggests, certainly not very often, in increasing the social good behavior, social self-control of the patient.

DR. BANCROFT: I think Dr. Abbott's paper very interesting and suggestive. We have tried the wet pack at Concord quite a little on a number of cases, and it seemed to me that it has had a temporary sedative effect and a permanent tonic effect on the cases in which we have tried it, particularly the cases of mania. I have been very much pleased in applying it to see how satisfied the patients were with the process. I recall only one case of excitement where a maniacal patient objected to the pack, and we were obliged after trying it for a week or two weeks to give it up because the struggles were so persistent, but in all the other cases in which we have tried it on maniacal subjects the patients have apparently liked it very much, and the first effect has been to make them quiet, and a number of the most excited cases have gone to sleep during the pack and have never made any particular objection to taking it. I think the wet pack as has been described to-night has this to say in its favor — it is cheap and does not require expensive apparatus, and can be used either in a private house or by any institution that is not provided with the more expensive apparatus for applying hydrotherapeutic measures. I think it is a therapeutic remedy that we should try in our cases. I have been disappointed, however, that the psychoses have not been modified in any way by this treatment. I cannot say that in any case in which we have tried it a mental cure has followed the pack. The improvement has been largely physical and sedative. A few cases have recovered, but I cannot say they recovered because of the application of the pack. The recovery came as it does in all acute cases at the proper time, and I cannot say that the application of the pack has hastened recovery, but I do think it is a help in these cases of excitement. I should recommend its use very strongly in such cases, particularly as a sedative.

(*To be continued.*)

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

NINETY-FOURTH ANNUAL MEETING, HELD AT ALBANY, JANUARY 30, 31 AND FEBRUARY 1, 1900.

PRESIDENT'S INAUGURAL.

THE first session on January 30th was opened by the Inaugural Address of PRESIDENT MACDONALD. This was brief, yet at the same time filled with valuable suggestions, and was received with scrupulous attention. After expressing his thanks to the Society for choosing him to preside over their deliberations, he took up the topic of a legal definition of the term "the practice of medicine," and proposed co-operation with the New York Academy of Medicine in order to establish such an interpretation as will exclude all forms of quackery. He suggested that the approval of the Society be withheld from State control of chronic infectious diseases until after the most careful consideration. He declared that the standards of the State Board of Examiners are the highest and most practical in the land and their work deserves the highest commendation. As to the schism between the Society and the American Medical Association, he said that the settlement was simple; let the Association admit the duly accredited delegates of the Society through the same door that was closed in the faces of the New York delegation at St. Louis; then the Association would be truly representative of the united medical profession of the United States. In his view of the field of national legislation on medical topics he took ground in opposition to the Gallinger Antivivisection Bill, and in support of the measure which Surgeon-General Sternberg has proposed for the increase of the medical corps of the army.

MEDICAL EXAMINERS.

Following the President's Address the State Board of Examiners, through their Secretary, DR. M. J. LEWI, reported 836 applicants for medical certificates examined and 165 rejected.

CARCINOMA OF THE STOMACH

was the first subject presented to the attention of the Society. DR. A. MCFARLANE, of Albany, read a paper and submitted cases showing increased hydrochloric acid.

AGE, SEX AND SEASON AS FACTORS IN NERVOUS DISORDERS

were discussed in a contribution by Dr. William C. Krauss, of Buffalo. He showed how each period of the life of men and women had its particular diseases, how conditions that were at one time harmless became at another productive of the greatest harm, and therefore how necessary it was to take into account questions of age, sex, seasons and general surroundings.

FACIAL PARALYSIS.

Dr. William M. Leszynsky, of New York, read this paper by title.

Dr. D. B. St. John Roosa, of New York, introduced the subject of

STRABISMUS.

At the last meeting of the Society, he observed, he called attention to a new operation for the cure of this defect. By this operation both muscles were stretched and divided at one sitting. Professor Panassi, of Paris, had performed 20 successful operations in the way referred to before reporting results, and since then Dr. Roosa and his colleagues had also performed many cases with success. It was important to the general practitioner to know that specialists in eye complaints could enter on these operations with knowledge as to what they were doing and a large amount of certainty as to the result. In 95 per cent. of cases they could ensure the removal of the deformity.

Dr. A. Edward Davis, of New York, followed with a paper showing what could be accomplished by means of non-operative treatment of strabismus.

THE DIFFERENTIATION AND TREATMENT OF OCULAR AFFECTIONS COMMONLY MET WITH IN FAMILY PRACTICE

was dealt with by Dr. Frank Van Fleet, of New York, who pointed out the great advances that had been made in connection with the treatment of ear diseases since it had engaged the attention of specialists. There was no reason why general practitioners should not make themselves familiar with all that had been ascertained in regard to the more common complaints, and so leave only the more obscure affections to be dealt with by specialists.

Dr. T. H. Halsted, of Syracuse, called attention to the significance of earache in children.

THE TEACHING OF THERAPEUTICS

was discussed in papers read by Dr. Eli H. Long, of Buffalo, and Prof. Reynold W. Wilcox, of New York, the former treating the subject in its bearing on undergraduates, while the latter referred to the instruction of post-graduates. Dr. Long said there were two things they had to deplore: on the one hand a growing skepticism as to the efficacy of drugs, and on the other an inclination to make a too ready resort to preparations. He thought they should protest against the dictation of the commercial houses as to therapeutics. In teaching it was best to commence with a consideration of the physiological conditions, and for this purpose the conference system was best adapted. Professor Wilcox said the problem of how to teach post-graduates was by no means a simple one. This was largely due to the fact that they had three classes to teach: (1) those who hold teaching positions in the smaller schools, and who want the latest information in regard to the results of discovery and research in matters pertaining to medicine; (2) recent graduates who elected a post-graduate instead of a clinical course in order to complete their training for the practice of their profession, and (3) the practitioners of several years' standing who wanted to learn all that was to be learned that would assist them in their practice. Post-graduate teaching was a failure unless it to some extent met the requirements of these heterogeneous classes. He confessed that sixteen years' experience had not enabled him to solve the problem with satisfaction to himself; but one conclusion he had arrived at was that, so far as possible, all such instruction should take the form of practical demonstration. Theories, new remedies, preparations, etc., were for the teachers to investigate themselves; as regarded their teaching, what was most important was that they should urge their students to attend cases in wards, and give them practical demonstration of what was being done.

THE CHARACTERISTICS AND SYMPTOMS OF WEIL'S DISEASE

were explained by Dr. Harlow Brooks, of New York, who also presented a pathological study on the subject.

Dr. A. Jacobi, of New York, in a paper entitled

THE TREATMENT OF TEMPERATURES AND HEART FAILURE,

described the ways in which it had been attempted to reduce increased temperatures. High temperatures he showed were not always dangerous, but on the contrary often exercised a minimizing influence on the disease. Where they were dangerous there was no reason why they should not endeavor to reduce the temperature, either by tonic treatment or by direct attack upon the micro-organisms.

Dr. James K. Crook, of New York, read a paper on

ACUTE CROUPOUS PNEUMONIA,

in which he discussed its pathogenesis and treatment in the light of the newer pathology. The efforts made to discover a serum for pneumonia, while not altogether satisfactory, were encouraging as far as they went; and considering the brilliant results obtained by the treatment of diphtheria, as well as what had been actually ascertained in regard to pneumonia, he thought there was good ground for believing that similar results would yet be achieved in connection with the latter disease. Incidentally the reader of the paper took exception to the opinion expressed in a published paper by Dr. Andrew H. Smith, that the condition of the lungs in pneumonia was not inflammation, but only a condition of germ growth. Dr. Crook agreed with him that the process was one of germ culture, but he thought that the condition might also be described as inflammation, though not analogous to other kinds of inflammation.

Dr. Andrew H. Smith, in opening the discussion on the paper, said he was pleased to know that Dr. Crook agreed with him as far as he did. At the same time he adhered to his previously expressed opinion, that pneumonia was purely a germ culture, and not at all properly describable as inflammation. The most important thing, however, in connection

with the discussion of the pathology of pneumonia was the fact of the double circulation of the lung. This fact had been overlooked to a singular extent in connection with the only disease in which its existence had an important bearing.

DR. H. P. HOPKINS, of Buffalo, thought that until pathologists and therapeutists made up their minds as to what was the proper germ to be attacked in pneumonia, general practitioners should remember the advice given by Dr. Jacobi in relation to another disease, and that was not to lose sight of the fact that every patient represented a separate individuality. In other words, they should attend to the constitution of their patients, and above all should not neglect hygiene and diet.

DR. CROOK, in replying on the debate, said he fully agreed with the last speaker as to the value of fresh air and diet; but while strengthening their patients' systems, it was also necessary to attack the cause of the disease by means of germicidal drugs or methods of treatment.

DR. WILLIAM H. THOMPSON, of New York, read a paper entitled

THE CLASSIFICATION OF INFECTIOUS DISEASES

in which he spoke of the harm that was done by labelling diseases infectious or contagious, and at the same time showed the confusion that existed even in the profession as to the use of these and other terms. Diseases of the kind usually thus described should, in his opinion, be divided into three groups. In the first should be placed diseases that are contagious and communicable, and for these the treatment should be isolation; in the second diseases that are non-contagious but communicable, and in these the treatment should consist of the destruction of the carriers of the infection; and the third of diseases which were inoculable, and these required specific treatment.

PROPHYLAXIS IN GYNECOLOGY.

A symposium of papers on this subject was next on the programme, but owing to the absence of several of the authors some of the papers had to be read by title. The full list was as follows: "Introduction," Dr. Henry C. Coe, New York; "Prophylaxis before and during Puberty," by Dr. W. Gill Wylie, New York; "Prophylaxis after Marriage," by Dr. Ralph Waldo, New York; "Prophylaxis in Obstetrics," by Dr. J. Clifton Edgar, New York; and "Prophylaxis in Gynecological Surgery," by Dr. William M. Polk.

STATE CARE OF TUBERCULOUS PATIENTS.

A special session of the Society was held in the evening in the Assembly Hall of the State Capitol for the purpose of considering the attitude that should be assumed to the State in regard to the care and treatment of tuberculous patients and the prevention of the spread of tuberculous infection. Members of the Legislature and the general public were invited to attend, and responded in goodly numbers. Several members of the Legislature took part in the speech making, and the result was a lively debate, the honors being carried off by the doctors, if the applause which they received was to be accepted as evidence of their success.

DR. EDWARD O. OTIS, of Boston, Mass., was the first speaker. He began by remarking that the fact that pulmonary tuberculosis was the most prevalent and destructive of diseases was proved by the mortality statistics of all countries. It was the cause of about one-seventh of all deaths, the proportion being three in twenty-two. It was worse where people were crowded together; it was contagious and therefore preventable, and it was a constant menace to the public health, because in large measure of the ignorance and carelessness of the people affected by it. The number of lives that could be saved would be the means of returning a large amount of the money expended in preventing the spread of the disease. Nearly all the countries of Europe had recognized the wisdom of making the matter one of State control, and several States in this country were now taking action in the same direction. The speaker then proceeded to describe the excellent results that had been obtained in Massachusetts, and expressed his hope that the people of New York State would succeed in their effort to get legislative action with the view to the establishment of a sanatorium and the adoption of other measures for caring for those afflicted with the disease and stamping out the disease itself.

DR. VINCENT Y. BOWDITCH, of Boston, followed with a detailed account of the work accomplished at the Massachusetts State Hospital for Consumptives at Rutland.

DR. EDWARD R. BALDWIN, of Saranac Lake, gave a cheering report of the results of the climatic and sanatorium treatment of the disease in the Adirondacks. Since the institution at Saranac Lake was established fifteen years ago, 1,200 cases had been treated. Of these three-fourths were in an advanced stage of consumption, and only a fourth in an incipient stage. The number of patients in an incipient stage was however, continually increasing, and so better results were obtained every year. In the last two years one-third had been in the incipient stage, and the results were: Twenty-three per cent. were discharged cured; in 56 cases the disease was arrested, 19 per cent. were improved, and only two per cent. died. They were careful to distinguish between complete recoveries and cases in which the disease could only be said to have been arrested, because it was necessary to allow some time to elapse to see whether the improved symptoms continued. Inquiries, however, which were being made showed that a large proportion of those in whom the disease had been arrested would, in course of time, be properly added to the number who had been cured.

DR. GEORGE BLUMER, of Albany, read a paper on the

INFECTIOUS CHARACTER OF TUBERCULOSIS AND THE PROGNOSIS OF INCIPIENT PULMONARY CONSUMPTION,

and DR. ENOCH STODDARD, of Rochester, dealt with the subject from the point of view of the duty and interest of the State in preventing the spread of infection.

The HON. HORACE WHITE, a member of the State Senate, heartily supported the proposed plans for taking charge of tuberculous patients, but the HON. OTTO K. KELSEY, a member of the Assembly, while expressing his personal sympathy in the movement, pointed out difficulties of a practical character that stood in the way, and made it extremely improbable that the Legislature would see its way to grant the

desired appropriation. There were, the latter speaker observed, enormous demands on the State for education, the care of the insane, prisons, canals, and a variety of other things, and for it to take care of all the people suffering from tuberculosis in the State — their number being estimated at 60,000 — was altogether too serious a matter to be entered on lightly.

DR. JOHN H. PRIOR, of Buffalo, replying to the last speaker, quoted figures to show that tuberculosis was increasing, and that the disease, accountable as it was for between 12,000 and 13,000 deaths a year, constituted such a serious state of matters as to call imperatively for State control. He ridiculed the idea that the burdens of the State were so great that it could not provide the small appropriation asked for, the object of which he reminded the members of the Legislature was not to make provision for all the tuberculous patients, but only to establish an experimental sanatorium, in which incipient cases could be treated with the view of discovering the best way of checking the spread of the infection. Even on grounds of economy, he ventured to say, it would soon be found that the money had been wisely expended. A number of other speakers continued the discussion, the preponderance of the opinion expressed being in favor of joint action by the State and local authorities, the former to establish the experimental sanatorium, and the latter to provide hospitals for advanced cases, and also to lay down and enforce regulations for stopping the spread of the infection. Members of the medical profession were urged to agitate the question among their patients and acquaintances, so as to educate public opinion, and get pressure brought to bear on the Legislature that would compel it to take action.

SECOND DAY.

The second day's proceedings commenced with a visit to the new Albany Hospital, where clinical papers and reports were read as follows: "Catheterization of the Female Ureters," by Dr. Charles P. Noble, Philadelphia; "The Modern Urethroscope; its Value and Limitations," by Dr. W. K. Otis, New York; "A Unique Case in Obstetrics," by Dr. F. H. Parker, Auburn; and "Uterine Fibroids, complicated by Pregnancy," by Dr. W. F. Ford, Utica.

In general session, the first subject to engage attention was

HUMAN AND BOVINE ANTHRAX,

on which a paper was read by DR. FRANK W. ROSS, of Elmira.

DR. JAMES LAW, of Ithaca, then gave a contribution on

BOVINE TUBERCULOSIS.

DR. V. A. MOORE, of Ithaca, entered into details as to the

PREPARATION AND USE OF TUBERCULIN,

with remarks upon the knowledge at present possessed of the difference between human and bovine tuberculosis.

In the course of the discussion which followed, DR. JAMES K. CROOK, of New York, described the clinical experiments he had conducted with tuberculin on human subjects at the New York Post-Graduate Hospital. The tuberculin had been obtained from the Board of Health, and everything possible was done to make the tests efficient, but the results were very unsatisfactory, and had quite discouraged him as to the utility of tuberculin in cases of human tuberculosis.

THE MEDICAL EXAMINER FOR LIFE INSURANCE AND HIS RESPONSIBILITIES

was the subject of a paper by DR. S. OAKLEY VANDER POEL, of New York, who showed that the medical officers of American insurance companies had been the first to commence the task of reducing physical disabilities and impairments to a scientific basis, the result being that now, instead of being compelled to reject a large proportion of the risks offered them, the companies were able to gauge the exact responsibility they were asked to undertake, and so know what to charge for the risk they assumed.

EXPERIENCE WITH THE ANGIOTRIBE.

Under this title DR. J. RIDDLE GOFFE, of New York, gave an account of various instruments that had been used for controlling hemorrhages, and said that the instrument he now showed had been used by him with almost invariable success. It was remarkable in these respects that it was only necessary to apply it for two minutes, and it had the extraordinary pressure of 3,000 pounds.

A paper by DR. EDWARD B. DENCH, of New York, on the importance of early recognition of

ACUTE INFLAMMATION OF THE MIDDLE EAR

by the general practitioner, was afterwards read. The early and free incision of the drum was advised, and the use of ear-drops, such as oil and laudanum, as emphatically condemned.

THE PRESIDENT'S ANNIVERSARY ADDRESS.

DR. WILLIS G. MACDONALD, in delivering his address on

THE RELATION OF THE CLINICAL LABORATORY TO MODERN SURGERY,

said there was an impression that the work of the modern surgeon was easier than that of his predecessors. So it was, for surgery was now an art that was much more certain in its results than formerly; but this very fact increased the surgeon's responsibilities, because the loss of a patient would not be so readily overlooked. It was more than ever necessary to guard against everything liable to produce septic conditions, and in this connection it was advisable to have their instruments and apparatus frequently examined. The laboratory also was of great aid to the surgeon in the way of providing analyses of the blood, urine, etc.

DR. SAMUEL G. GANT, of New York, gave an exhibition of

RECTAL INSTRUMENTS.

DR. F. H. PARKER, of Auburn, described a

UNIQUE CASE IN OBSTETRICS,

in which a dead fetus was removed from a woman after having apparently been in the womb for two years, and a few days after its removal she was delivered of a fully developed and healthy child.

DR. ROSWELL PARK, of Buffalo, contributed the results of some further investigations he had made since the last meeting of the society into the cause of cancer. The information which was being collected

at the State Laboratory went far, he said, to confirm the opinion as to the parasitic nature of cancer.

DR. GEORGE H. FOX, of New York, described the method by which it was now found possible to effect a complete cure of leprosy. He mentioned a number of cases, among them that of a gentleman who was now carrying on business as a merchant in New York, in which the most happy results had been obtained. While not ignoring the importance of chaulmoogra oil, he insisted strongly on the benefit that was imparted to patients by a cheerful prognosis.

SOME QUESTIONS ABOUT THE CARE OF THE HAIR

were discussed by DR. GEORGE THOMAS JACKSON, of New York. Incidentally he advised against the custom of shaving the heads of patients in fever and other cases, the advantages being doubtful, and the results, especially to women, being much inconvenience and unnecessary annoyance. For the ordinary treatment of the hair, he recommended the use of a little pure pomade. There was no custom more absurd than that of singeing the hair.

DR. ROBERT C. MYLES, of New York, contributed some remarks on the

SURGERY OF THE NASAL SEPTUM AND THE TURBINAL BODIES,

illustrating the same with anatomical specimens.

At this point in the proceedings, the REV. DRS. RAYMOND, President of Union University, and BULKLEY, editor of the *Christian Advocate*, were introduced, and papers of an interesting popular character were delivered, Dr. Raymond pleading for the requirement of a more liberal education of medical students, preparatory to their entrance on their purely professional studies, whilst Dr. Bulkley made a scathing exposure of the Christian Scientists and their subtle methods for imposing on the public. A suggestion by the latter that the medical profession should undertake the task of bringing all classes of quacks to justice called forth a protest from DR. JACOBI, who remarked that the previous efforts it had made in this direction had been so unfortunate in their results as to constitute a serious warning against their attempting anything of the same kind again. The proposals of Dr. Raymond in regard to the more liberal education of medical students were endorsed by Dr. Jacobi and others, and a standing vote of thanks was given to both reverend gentlemen for their addresses.

DR. A. M. PHELPS, of New York, exhibited a number of braces that were commonly used in the treatment of hip-joint diseases and among them the Phelps brace, a male child with the latter on his limb being shown, and the doctor giving ocular demonstration of the fact that he could, so to speak, play football with the boy without causing him the slightest pain.

DR. JOHN O. LEE, of Rochester, read by title a paper on

FRACTURES OF THE WALLS OF THE MAXILLARY ANTRUM.

DR. WILLIAM MABON, of Ogdensburg, read by title a paper on

SURGICAL OPERATIONS IN HOSPITALS FOR THE INSANE.

DR. H. BEECKMAN DELATOUR, of Brooklyn, made a contribution to the surgery of the stomach, in which he described a number of cases of gastrotomy and gastrectomy.

DR. F. W. SEARS, of Syracuse, called attention to the large number of instances in which sepsis was caused by the neglect of proper precautions in puerperal cases.

THIRD DAY.

At the beginning of the third day's sitting a report was presented from the committee appointed to consider the feasibility of getting a law passed to provide for the registration of medical experts. The opposition of the legal profession to any legislation of the kind proposed was so pronounced that the committee did not see any prospect of any law of the kind desired being enacted, and therefore recommended that they should be discharged, a suggestion which it was agreed to act upon.

A motion was passed expressing approval of the experimental work being done by the cancer hospital at Buffalo, and providing for the presentation to the Legislature of a memorial asking that the appropriation be continued.

DR. LUZERNE COVILLE, of Ithaca, presented a paper showing the

SHAPE OF THE SPLEEN AND ITS RELATION TO THE CHEST WALL AND ABDOMINAL VISCERA,

a subject on which, he remarked, the teaching of the text-books was vague and to a large extent contradictory.

DR. I. S. STONE, of Washington, D. C., submitted a paper entitled

SUPRAVAGINAL HYSTEROMYOMECTOMY,

accompanied by a series of cases in which tumors had been removed from the uterus.

DR. F. W. HIGGINS, of Cortland, read a paper on

ATRESIA OF THE VAGINA.

DR. W. FREUDENTHAL, of New York, described a case in which cerebrospinal fluid was discharged through the nose.

Among the remaining papers, most of which were read by title, was one by DR. THOMAS P. SCULLY, of Rome, dealing with

INGUINAL HERNIA,

and showing the comparative results of radical treatment by operation and treatment by injection. A larger percentage of cures by operation, he observed, could be claimed now than at any former period, but many persons preferred irrigations, and it was found that many cases could be successfully dealt with in this way.

DR. A. M. PHELPS, in discussing the paper, referred to the large number of cases of relapse which he had been called upon to handle at the New York City Hospital, in consequence of the inefficient treatment elsewhere by means of irrigations and trusses.

The attendance at all the sessions was large, and great interest was displayed in all the business and social sessions. At the closing session of the Society the following officers were elected for the ensuing year: President, Dr. A. M. Phelps, of New York City; Vice-President, Dr. George Seymour, of Utica; Secretary, Dr. F. C. Curtis, of Albany; Treasurer, Dr. O. D. Ball, of Albany.

At the close of the programme, votes of thanks were passed to the retiring president and others, and the new President, DR. PHELPS, having been installed, made a few happy remarks in appreciation of the honor conferred on him, and promising his best endeavors to fill the chair with advantage to the Society.

In the course of their visit the delegates were accorded a reception by Governor Roosevelt at the State House, and there was also a grand dinner at the new Ten Eyck Hotel, the attendance at which was unusually large, and the speeches of more than ordinary interest.

Recent Literature.

Twentieth Century Practice. An International Encyclopedia of Modern Medical Science. By Leading Authorities of Europe and America. Edited by THOMAS L. STEDMAN, M.D., New York City. In twenty volumes. Volume XVIII, "Syphilis and Leprosy." New York: William Wood & Company. 1899.

Two subjects, syphilis and leprosy, and three contributors occupy the whole of this volume of seven hundred and three pages of the "Twentieth Century Practice." The subject of Acquired Syphilis has been entrusted to Dr. E. Lang, professor of dermatology and syphilology at Vienna, the successor of Sigmund. A more competent person could hardly have been selected. In 1871, in his inaugural address as professor at the University of Vienna, Lang advanced the view that the syphilitic contagium must be a living organism, having the faculty of multiplying in healthy individuals, a view which he still maintains and explains thereby the pathological phenomena manifested by the disease process. At the same time, he distinctly recognizes that we have not yet acquired a clear knowledge of the character of the syphilitic contagium.

Lang holds that persons who have once had constitutional syphilis are rarely susceptible to a new infection, but there is no absolute immunity, and he states that he has almost every year occasion to observe cases of reinfection. He considers that clinical and experimental researches make it absolutely certain that a person does not become constitutionally diseased immediately after infection. In the matter of prophylaxis he is of the opinion that even the smallest lesion in a person who has had contact with a suspicious secretion should be carefully cauterized. If one can succeed in totally excising the initial lesion, the patient is frequently saved from an attack of constitutional syphilis — especially if this is practised before there is any enlargement of the inguinal glands. In regard to constitutional treatment, for general practical application, Lang seems to prefer inunction.

Lang's monograph occupies three hundred and sixty-nine pages, or more than half the whole volume. It is a worthy exposition of a most important subject, in which the author has deserved authority.

Dr. Jonathan Hutchinson contributes a short, terse article of twenty-seven pages on Inherited Syphilis. Hutchinson's position in regard to this subject is too well known to need further comment, but no one has a better right to form and to hold opinions upon it.

Dr. Prince A. Morrow, of New York, contributes the section, one hundred and seventy-nine pages, upon Leprosy, a subject which assumed additional interest for the inhabitants of this country when we made ourselves responsible for the Hawaiian group of islands. Dr. Morrow is a contagionist. As to the modes of contagion, he thinks it very probable that they are many, but that the precise manner in which the leprous virus is transferred from one individual to another is unknown. He is, however, more than ever impressed with the conviction of the widespread prevalence of infection through the upper air passages, whilst admitting the error of supposing that there is any one *exclusive* mode of infection.

Interstitial Gingivitis, or So-called Pyorrhœa Alveolaris. By EUGENE S. TALBOT, M.D., D.D.S., Professor of Dental and Oral Surgery, Northwestern University, Woman's Medical School. With 73 illustrations. Philadelphia: The S. S. White Dental Manufacturing Co. 1899.

The author devotes the first sixty pages of this exceedingly interesting book to the history of the disease and to the study of the histology and the microscopic anatomy of the jaws and the epithelial structures associated therewith. The author has evidently gone carefully over the literature of these subjects, and has selected the best for his readers' consideration. He has supplemented this with the results of his own observation and the reader is able to gain a clearer insight into the development of these parts than is accorded by many of the text-books on the subject. As to the uric-acid theory of this disease, the author says: "Uric acid when found is merely an expression of the uric-acid diathesis and is a coincidence." To support this view the author points to careful chemical examinations made in several thousand cases which gave only six per cent. in which uric acid could be observed. Attention is called to the excretion of large quantities of inorganic salts through the salivary glands, and to the irritation and inflammation which arises from this cause. This is especially true of children and is put down as one of the important causes of interstitial gingivitis. The author gives a careful list of predisposing and exciting causes of this disease, and brings to bear an overwhelming amount of evidence to support his views. He treats of the constitutional effects which may be produced, especially in the suppurative stages of the trouble, and gives careful attention to the prevention and cure of the disease. The book is a distinct addition to our knowledge of this subject and deserves the attention of both physicians and dentists.

General Pathology. By ERNST ZIEGLER, M.D. Translated from the ninth revised German edition. Edited by ALBERT H. BUCK, M.D., New York. New York: William Wood & Co. 1899.

The appearance of an English translation of this famous text-book cannot fail to be welcome to the English-speaking medical profession. In this, the ninth edition, the number of illustrations has been increased from 458 to 544. This adds greatly to the usefulness of the work.

The chapters on Retrograde Disturbances of Nutrition and Infiltration, and on Tumors show the greatest changes and alterations. The author divides the different kinds of degeneration which lead to the formation of hyaline products into four groups. These com-

prise (1) colloid and epithelial hyaline concretions; (2) pathological cornifications of epithelium; (3) amyloid degeneration of connective tissue and amyloid concretions; (4) the hyaline degenerations of connective tissues. Mucous degeneration is not included in these groups. The tumors are divided into three groups: (1) Tumors of the connective substances; (2) epithelial tumors, and (3) terat id tumors and cysts. The group of the epithelial tumors is divided into two lesser groups; one containing the papillary epitheliomata, the adenomata and the cystadenomata, the other including the carcinomata and the cystocarcinomata. Regarding the etiology of tumors the author takes an agnostic position. He does not accept Ribbert's theory that the main cause of tumors is the separation of individual cells from their normal situations, nor does he accept the parasitic theory. The so-called infectious granulomata are not classed with the tumors.

The translation is the work of a number of collaborators and has been well done. The book is attractively printed and bound.

Encyclopedia Medica. Under the general editorship of CHALMERS WATSON, M.B., M.R.C.P.E. Volume I, Abdomen to Bone. New York: Longmans, Green & Co. 1899.

It is proposed to issue this encyclopedia in twelve octavo volumes to be published quarterly, each volume to have at least 500 pages. The purpose of the publication, as announced, is to furnish medical men with a work which, differing from all existing ones, would be a complete and authoritative medical and surgical library in itself — concise, practical, up to date, easily referred to and at a moderate cost.

The present volume has fifty-nine headings of subjects. The list of contributors exhibits many names well known within and beyond the United Kingdom. Among others we notice those of Dr. Dreschfeld, of Manchester, Dr. Clouston, of Edinburgh, Dr. Rolleston, Dr. Theodore Williams, Dr. Patrick Manson, Dr. Lauder-Brunton, of London, Dr. Ogston, of Aberdeen, Dr. Byrom Bramwell, of Edinburgh, Dr. Robert Saundby, of Birmingham. It is proposed to deal with subjects at a length proportionate to their importance. This volume contains 579 pages; its size and general appearance are most satisfactory.

Loveliness. A Story. By ELIZABETH STUART PHELPS. Boston and New York: Houghton, Mifflin & Co. 1899.

This story, appearing first in the *Atlantic Monthly*, has been republished in book form. It is clearly written for a purpose, that purpose being an attack on the practice of vivisection. Loveliness is the name of a dog, owned by a wholly abnormal child. The dog is stolen, and is rescued at the last moment, when about to be the subject of a vivisection experiment, and restored to its pining mistress. The details we omit, merely remarking that they are quite unnecessarily harrowing and misleading. Our criticism of the book lies in its maudlin sentimentality. A serious question, about which, no doubt, there may be a certain legitimate difference of opinion, is treated wholly from an emotional standpoint and hence the argument has absolutely no significance. May we not ask that the opponents of vivisection at least approach the discussion of it in a dignified manner?

THE BOSTON

Medical and Surgical Journal.

THURSDAY, FEBRUARY 15, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

HUMAN VIVISECTION.

WE hear it said and see it written in certain quarters, that the use of animals for experimental research and the advancement of medical knowledge is but the stepping-stone or prelude to the use or further use of human beings for the same purposes. In fact this is one of the arguments or appeals to sensibilities freely put forth by antivivisectionist agitators to fire the hearts of their followers and to secure new converts among those who are disposed to listen to reason and argument. It is not a suggestion or an accusation which the profession can afford to treat lightly or with disdain, much as we might be disposed to do so in our own country at least. It must be treated seriously and with earnest searching of the heart.

With the seventh sons of seventh sons, with natural bone setters, with layers on of hands, with those pseudo-scientists who derive their powers from supernatural sources — in fact, with all that class of pretenders who would reap where they have not sown and gather where they have not strewn, who would draw knowledge from the vacuity of ignorance, it is idle to confer and to such we do not address ourselves. But there is a large class of thoughtful, conscientious, well-balanced people to whom the physiological laboratory and the clinical wards of a hospital are a source of misgiving and honest perplexity. Their sensibilities should be carefully considered and their hesitancy reassured. Doctors as a class, and the doctor as an individual, are not inhuman. They are in fact very human, or let us say humane, quite as much so as the average citizen; we are willing to go farther and affirm that we believe they are more so.

We do not believe that in this country, at all events, patients either in or out of hospitals are deliberately or knowingly treated by doctors with cruelty, with recklessness or thoughtlessness. We do believe that educated physicians are guided by the golden rule more constantly, and even exceed it without any reasonable hope of a retroactive benefit more frequently, than any other class in the community.

Their greatest happiness is in the increase of sound knowledge, and their greatest reward lies in a capacity for increased usefulness to their fellow-men. We believe it is generally recognized by the profession that zeal should stop short of indiscretion, and that a thirst for knowledge should stop short of curiosity.

The attitude of the violent antivivisectionist is much that of the Middle-Age persecutor of the anatomist. It is generally admitted to-day that anatomy must be studied upon the cadaver, and in the same way it is a reasonable proposition that the care and cure of the sick must be learned in presence of the sick. The sick themselves often profit by the necessarily more thorough study of their condition, and not a few are grateful for the opportunity to be of some service to mankind. There must inevitably be some first time for the administration of a new drug and some first occasion for the performance of a new operative measure. We believe, however, that in both these procedures the experiment, if such it is to be called, is hedged around with every possible precaution. The physician or surgeon who would resort to either at the cost of distress or danger to his patient, without a reasonable hope of averting some worse evil or without the consent of the patient, would not be supported in such action by his professional colleagues.

One has only to ask what would suffering humanity lose to-day without salicylic acid and without laparotomy.

Notwithstanding the almost universal recognition of the indispensableness of the sick for clinical teaching, the profession itself is constantly seeking new sources for the instruction of students to supplement the hospital ward and to minimize the repeated examination of the individual patient. In support of this assertion we would call attention to an article in the issue of the JOURNAL for January 11th of this year.

In general, we believe that our fellow-citizens in this country and in this community not only can have but will do well to have and to show confidence in their educated professional men, of whatever walk in life.

STATE CARE OF THE INSANE.

THE newly-created State Board of Insanity has presented to the Massachusetts Legislature its special report, as required by the acts of 1898, whereby the Board was directed to suggest "such method or methods as in its opinion will most effectually provide for the care and support of the insane poor who, under existing laws, are cared for by or supported at the expense of the cities and towns of the Commonwealth," including plans for the remedial treatment of the curable insane and for the care of the convalescent insane.

Including the School for Feeble-Minded, the epileptics, the drunkards and the 112 children in the hospital cottages, of whom 23 are feeble-minded and 89 epileptic, there are under the supervision of the Board: (1) in the State institutions, including the criminal insane and insane criminals, 6,425 insane persons, of whom fully 90 per cent. may fairly be considered incurable; (2) in the Boston Insane Hospital 507; (3) in private hospitals 237; (4) in city or town almshouses 1,213; (5) at board in private families 224 — in all 8,606.

During the last ten years the increase in the number of the insane in the State insane hospitals and in the Boston Hospital for the Insane has averaged 271,04 yearly.

With regard to the care of the acutely insane who are curable and of convalescents, the propositions of the Board will probably be universally commended by those competent to form an opinion, namely: (1) That the acutely insane should not be delayed in coming under the best medical care; (2) that they should not be compelled to suffer the exhaustion of a long journey to a distant hospital, nor to take unnecessary risk of detention in a station-house; (3) that they should not be removed too far from their friends.

The recommendations of the Board will generally be accepted as wise, regarding these curable insane, that provisions for their treatment be made in connection with the hospitals for the insane now in existence by securing small houses at such distances from the hospitals as may be deemed best; such cottages or houses could be built or bought or hired. Of course, the curable insane will continue to be treated in the private hospitals and by competent physicians, so far as their means can afford them, in private houses in suitable cases. But too large a number must be sent to the public hospitals, in the absence of sufficient provisions for the treatment of patients with small means in our one corporate hospital for the insane; and for them it is only simple justice to place them elsewhere than in institutions crowded with the chronic insane. The Board very properly desires more time to study the problem before committing itself for or against a recommendation of a new hospital for the curable insane.

For the care of the increasing number of the chronic insane, the Board recommends that 2,000 acres of land be bought for gradually developing a colony for the insane. This plan has already proved to be a success in France and Germany and this country; it has been adopted by the Massachusetts School for the Feeble-Minded, it will be part of the hospital for epileptics in this State and we hope that the recommendations of the Board in this respect, perhaps with some modifications, will commend themselves to the Massachusetts Legislature.

The Board evidently expects that a small number of the incurables who are harmless and not needing constant or frequent attention from physicians will be boarded out in private families, but in a community like that of New England the number must be limited, although that limit is not yet reached.

The Board advises that "as soon as may be after the first day of January, in the year 1904, the

State Board of Insanity shall transfer and remove all insane persons dependent upon public charity within the Commonwealth, who are not cared for in any hospital, asylum or receptacle maintained by the Commonwealth, to such hospital, asylum or receptacle, so maintained, as the said Board of Insanity may deem expedient." This provision involves the transfer of 5,607 insane persons who are now "cared for or supported at the expense of cities and towns," to be supported by the State — in round numbers, two-thirds of the insane under the supervision of the Board. There can be no doubt as to the soundness of the general statement of the Board that all of the insane must be cared for under conditions absolutely controlled by it, and if in institutions, only in such as are owned or controlled by the Commonwealth.

We believe that all the local almshouses containing insane inmates should at once be required to get licenses from the State Board of Insanity, provided their condition be approved by the Board or made conformable to the Board's requirements. Failing that, the inmates should be sent to some institution owned by the State. At the end of four years the license system could be given up, if the Board's plan is adopted.

This is a matter that interests not only Massachusetts but all the States of the Union, and some of the States, notably New York, have already taken steps in this direction.

CLINICAL INSTRUCTION IN SMALL SECTIONS.

ALL signs are pointing toward definite changes in medical teaching in the near future, and it is already easy to see in what direction one of these changes is likely to be made. The reaction from the merely didactic lecture has been extreme, due no doubt to the growing feeling that the preparation for the practice of medicine, to be adequate, must be at first hand from patient to student, rather than through the mediation of an instructor, however gifted he may be in the exposition of his subject. It has long been recognized that such direct contact between the student and the subject studied is desirable, but the difficulties in the way of bringing about the proposed results have been manifold and apparently insurmountable, because of the increasing numbers of students on the one hand and the relatively few available patients on the other. To give each student an opportunity to work out for himself the problems of diagnosis has seemed a practical impossibility, which time has tended to increase rather than diminish. Hence has arisen the so-called clinic to large classes, a very much more valuable exercise than a lecture without practical illustration, but still falling far short of the ideal of instruction, owing to the practical non-participation of the students. By degrees the demand has grown, until now it appears that means must be found to meet it, that the student, during his course of medical study, shall have the opportunity of working out for himself the questions and difficulties which individual cases present. This means section teaching, which again requires many patients and, what is of equal practical importance, many instructors.

We are glad of this opportunity to call attention to a paper by Dr. A. H. Wentworth, printed elsewhere in this issue, which opens the way to an application of the principle of section teaching in general, with particular reference to the needs and opportunities of the Harvard Medical School. A reading of the pages will show that Dr. Wentworth has worked out a careful scheme, which permits each student in a given class to examine for himself a large number of patients, suffering from a variety of diseases, and therefore to gain an insight into various affections from his own investigations. In other words, we have here a demonstration of the possible working of a system which is sufficiently comprehensive in its scope to be of actual value. It is hardly necessary to say that we are in complete agreement with Dr. Wentworth in his insistence that this is the right way to teach clinical medicine and clinical surgery. We are also in agreement with him in the opinion that the didactic lecture, as we have continually had occasion to urge, is not relegated to a subordinate place by this plan, but simply increased in importance and dignity. The student will need more than ever before to have the relations of the subject and its bearing upon other subjects put before him in concise and systematic form, and this it should be the function of the heads of departments to do, and do well, a much harder task than they have ordinarily been called upon to perform.

It is evident that the method of teaching in small sections will demand an increased teaching force. This must be met fairly before the plan can, by any possibility, succeed. To expect one teacher to do justice to a large number of students or to himself in such practical instruction is out of the question. To obtain good teachers in sufficient number is therefore absolutely demanded. This should not be difficult in any progressive medical community, where young men are eager to teach and to learn through teaching. Just here, in our opinion, lies one of the chief merits of the system, in that it is sure to make better teachers as well as better students. To teach half a dozen men well, exposed to their questions asked under no restraint, is a test of ability which the lecture at a distance does not entail.

Provided the ordeal be not too great for the patients and their interests be carefully safeguarded, we see no reason why Dr. Wentworth's scheme of rotation should not meet with complete success. Taken in connection with Mr. Cannon's plan of case teaching recently discussed in the JOURNAL, as a supplement to the almost inevitable deficiency of available patients, we certainly have here outlined a plan of systematic teaching, quite superior in practical usefulness to anything heretofore proposed.

DUST STORMS ON BOSTON'S BACK BAY.

THE Boston Society for Medical Improvement will devote its next meeting, Monday evening, February 19th, to a consideration of the dust nuisance, especially as manifested in the streets of Boston, and particularly in the streets of its principal residential districts. If things continue as they have been, those who move and try to have their being in that district must clothe themselves and their houses, too, in brown khaki and wear respirators of antiseptic construction. The trials to which our fellow-citizens are exposed in dry weather are only surpassed by those which afflict Thomas Atkins on the veldt or karroo of South Africa. Whether the remedy is to be found in asphalted streets or in some other treatment, we trust that the Improvement Society will determine. Various experts will lend their aid, some to show us bacteriologically the micro-organisms with which the internal and external economies of the indigenous are loaded up, and others to suggest how the Back Bay may be made uncomfortable for the dust instead of the dust making it uncomfortable for human beings. It is reported that for the benefit of strangers who may not have seen a Back Bay dust storm a moving picture of this phenomenon of no more than ordinary virulence will be projected upon the screen by the aid of the calcium light — a chronomotographic dust storm.

It is also rumored that some statement will be made in regard to the usual disposition of the taxes collected for street watering. There will doubtless be a large attendance at this meeting, drawn thither as well by recollections of the past as by hopes for the future, by a sense of individual suffering as well as by a scientific zeal for the welfare of the human race, for which in a measure the members of the medical profession are trustees.

MEDICAL NOTES.

PLAGUE. — A decree has been issued at Lisbon announcing that plague has disappeared from Oporto and that the quarantine of that port has been raised. Recent information from Honolulu shows that the plague situation there has greatly improved. Another regular officer of the Marine-Hospital Service, Dr. Sanford, has been sent to Honolulu to assist Dr. Carmichael, the officer stationed there. The city of Honolulu is assisting these officers in every possible way and has appropriated $118,000, which is to be used for the erection of a filtration plant to ensure a pure water supply. The city has also made arrangements for the construction of a new drainage system. It is estimated that the expense incurred in connection with plague in Hawaii will not be under $1,000,000. In Manila plague is reported as being on the increase, and is creating considerable excitement and alarm. It is still prevalent at Hong Kong.

THE NAVY MEDICAL CORPS. — It is reported that Secretary Long has prepared a bill designed to encourage men to enter the Medical Corps of the Navy, where there are invariably more vacancies than candidates. The bill proposes to increase the rank of assistant surgeons (the grade that new men take on being commissioned) to that of junior lieutenant instead of continuing it at ensign, which it has been since the Civil War. This, it is hoped, will remove the objection regarding subordinate rank. Seven vacancies now exist for which a board is waiting at the New York Navy Yard to examine candidates. Any young doctor having good credentials may take this examination, and if he meets requirements the commission follows without the exercise of political or other influence.

A NEW METHOD OF GAS POISONING. — A fatal accident to the owner of a gas coin and slot machine was narrowly averted a few days since. The machine is designed to let into the house pipes a certain amount of gas for every silver twenty-five-cent piece dropped into the slot. The owner of the machine went to bed leaving the gas burning and when the gas was exhausted the light naturally went out; later a friend seeing that the gas was no longer burning dropped another coin in the slot, with the result that the gas escaped and nearly asphyxiated the owner of the machine. It might be wise to limit the application of the slot machine to less dangerous uses.

SMALL-POX IN NEW BRUNSWICK. — The New Brunswick Government officials are enforcing the health regulations in several counties in view of the outbreak of small-pox. The disease was brought to New Brunswick from the Province of Quebec, where a total of 280 cases have appeared up to February 7th. There are about 60 cases in New Brunswick, making about 340 in eastern Canada.

INFLUENZA EPIDEMIC IN MUNICH. — In Munich it is reported there are 60,000 cases of influenza, which has spread throughout Germany. In Berlin recently every bed in every hospital was occupied, and the hospital physicians are being severely taxed to properly care for their patients.

FAMINE IN RUSSIA. — The Imperial Bureau of Medical Affairs has issued a memorandum concerning the famine in the Government of Bessarabia, showing that $200,000 has been assigned for the relief of distress in that district. Sixty-nine thousand men are without work.

MORTALITY IN BOMBAY. — The number of deaths in Bombay, February 6th, was unprecedented, with a total of 408. The situation is aggravated by the advent of famine refugees.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, February 14, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 82, scarlatina 56, measles 84, typhoid fever 5.

OFFICERS OF BOSTON CITY HOSPITAL ALUMNI ASSOCIATION. — At the annual meeeting of this Association held February 6th, the following officers

were elected: Dr. John H. McCollom, President; Dr. Charles F. Withington, Vice-President; Dr. W. H. Robey, Jr., Secretary; Dr. W. H. Prescott, Treasurer; Dr. Paul Thorndike, member of the Executive Committee. At the annual dinner which followed the business meeting at Young's Hotel, about 80 members were present from different parts of the New England and other States. Dr. W. P. Bolles presided. The speakers were Mr. H. E. Bolles, who represented the legal profession, Drs. D. W. Cheever, J. G. Blake, George B. Shattuck, E. H. Bradford, C. J. Blake, Abner Post, J. H. McCollom. Dr. G. B. Henshaw, of Cambridge, read a poem.

ANNUAL MEETING OF THE CORPORATION OF THE MASSACHUSETTS GENERAL HOSPITAL. — The annual meeting was held February 6th. The election of officers resulted as follows: President, Charles H. Dalton; Vice-President, Francis C. Lowell; Treasurer, Franklin Haven; Secretary, Thomas B. Hall; Trustees on the part of the Corporation, Francis Blake, Edmund Dwight, Reginald Gray, Nathaniel Thayer, Henry P. Walcott, Samuel D. Warren, George Wigglesworth, Moses Williams. Four more trustees are to be appointed by the Commonwealth.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday, February 19th, at 8 o'clock P. M. The subject of the "Street Dust Nuisance" will be discussed. Remarks are expected by Dr. Vincent Y. Bowditch, Dr. Samuel W. Langmaid, Dr. Clarence J. Blake, Clifford Richardson, Esq., of New York, Prof. William T. Sedgwick, Prof. C. Frank Allen, and other prominent gentlemen. Arthur K. Stone, M.D., Secretary.

BOSTON SOCIETY FOR MEDICAL SCIENCES. — At a meeting of the Society held Tuesday, February 6th, papers were presented by Dr. H. G. Beyer and Dr. H. C. Ernst. Dr. Beyer spoke of some recent researches on "The Relation between Mental Work and Physique," with the general conclusion that such a relation actually exists. Dr. Ernst gave an interesting account of the "History of the Microscope," illustrated by many lantern slides.

JANUARY MORTALITY STATISTICS OF NEWTON, MASS. — The mortality statistics of Newton for January give the total number of deaths at 45, and the death-rate for the month 19.57. During the month more than 100 cases of contagious disease were reported, a large proportion being diphtheria.

NEW YORK.

A CASE OF IMPORTANCE. — A life insurance case of considerable interest and importance has recently been decided in the courts. A suit brought to recover upon an insurance policy issued by the Metropolitan Life Insurance Company upon the life of one Patrick O'Farrell was dismissed on the first trial for breach of warranty in giving a false answer to the question, "Did any of the parents, grandparents, brothers or sisters of the life proposed ever have consumption or any pulmonary or scrofulous disease?" To this question the medical examiner put down the answer, "No." It was afterwards ascertained that a brother and sister of decedent had died of consumption. A new trial was granted on appeal, the Second Apellate Division of the Supreme Court holding that the beneficiary might show that, although the insured gave a true answer to the question, the physician wrote it down incorrectly. On the second trial an agent of the company, who was present at the time when the medical examination was had, testified for the plaintiff to the effect that in reply to the question the insured stated that he "did not know." The medical examiner testified that he put down the answers as given by the insured correctly, and read them over after they were written down, when the insured signed the paper. A judgment for the plaintiff on the second trial, upon the verdict of a jury, has now been affirmed on appeal, the court holding that the insurer could not predicate a breach of warranty upon the falsity of the answer thus written by the medical examiner.

REPORTED RECOVERY FROM FRACTURED SPINE. — On February 6th, Bartholomew Moriarty, a hod carrier, sixty-five years old, was discharged as cured from St. Joseph's Hospital, Yonkers, where he had been under treatment for two months for a fracture of one of the cervical vertebræ. The fracture was clearly shown by x-ray examination and was the result of a fall from a building the last of October. He was at first treated by a private physician and appears to have made a partial recovery. Later, however, he began to suffer much pain and his left side became paralyzed from pressure on the spinal cord, and on December 8th, he presented himself at the Yonkers hospital, having hobbled in his disabled condition all the way from his home in Dobb's Ferry, a distance of five miles.

THE MOUNT SINAI HOSPITAL. — At the annual meeting of the managers of Mount Sinai Hospital, held January 28th, it was reported that $531,682 (less a mortgage of $80,000) had been paid for the plot of ground for the new hospital, and that the fund for the erection of the buildings now amounted to $439,175. It was stated that in consequence of the advance in the price of materials the cost of these will be considerably greater than was anticipated. Of the 3,065 patients admitted during the year over 81 per cent. were free. The number of deaths was 408, against 325 in the previous year. The number of operations were 2,098, a considerably larger number than in any previous year. The total number of patients treated in the hospital, dispensary and district service was 36,731.

ANNUAL BULLETIN OF STATE BOARD OF HEALTH. — The annual bulletin of the State Board of Health shows that the number of deaths in the State in 1899 was 121,820, an excess of about 850 over those in 1898, and of 2,550 over the average of the past ten years. The mortality among children under five was

1,800 less than in 1898, and nearly 5,000 less than the average for ten years; 29 per cent. of the deaths occurring in those under five, against the average of 35 per cent. In the maritime district the deaths under five were 1,100 fewer than in 1898.

Infirmary for Vassar College. — Mrs. Caroline Atwater, a resident of Poughkeepsie and one of the alumnæ of Vassar College, has doubled her original gift of money to the college for a new infirmary, on account of the great increase in the cost of building materials. Vassar, it is said, was the first college in the world to establish an infirmary of its own, having had one in the main dormitory ever since the original buildings were erected. The growth of the institution has rendered a separate infirmary building necessary, and the means for this are now supplied by Mrs. Atwater.

An Inaugural Address. — On February 12th, Dr. Robert F. Weir delivered his inaugural address as president of the Medical Association of the Greater City of New York. In the scientific portion of it he took for his subject "The Formation of an Artificial Anus," and the paper was discussed by Drs. Robert Abbe, W. Gill Wylie, A. G. Gerster, Wm. B. De Garmo, Frank Hartley, and other well-known surgeons.

Two Centenarians. — Mrs. Mary Ann Matthieu, of Oswego, N. Y., died recently, aged one hundred years, eight months. Sagie Evans, an English gypsy who was held in great reverence by her tribe, died in her tent, near Elizabeth, N. J., last week, at the age of one hundred and six. She was born in Northamptonshire in 1794, and had lived all her life in tents.

Testimonial to John Kelly. — At a conference of the political friends of the late John Kelly, held February 7th, it was decided that a contemplated testimonial to his memory should take the form of a nonsectarian ward of ten beds in St. Vincent's Hospital. Such an endowment is estimated at $30,000, and one-half of this amount has already been subscribed.

Society for Instruction in First Aid to the Injured. — The report of the Society for Instruction in First Aid to the Injured shows that since its establishment by the State Charities Aid Association, in 1882, 11,929 persons, including a considerable number of members of the Police and Fire Departments, have attended the Society's classes.

Alterations at Long Island College Hospital. — Plans are being prepared for the erection of a new fire-proof building to replace the central section of the Long Island College Hospital in Brooklyn. The new structure is to be four stories high, and will cost about $150,000.

Cremations in New York City. — The fact that a new cemetery is to be opened on Staten Island for the burial of the dead of Greater New York has brought out the other fact that out of the 60,000 people who annually die in the city, only 600 are cremated.

Paper on Medicine and Physicians. — At the February meeting of the New York Historical Society, a paper was read by Dr. Sidney H. Carney, Jr., on "Medicine and Physicians in the City of New York in the Year 1800."

Miscellany.

ADDITIONS TO QUARANTINE REGULATIONS.

Department Circular No. 6 of the Marine-Hospital Service, makes various additions to the quarantine regulations of the United States and its dependencies, designed to prevent the introduction of the plague. Among the additions of special interest are the following:

Passengers should not be vaccinated at nor *en route* from ports or places infected with plague. Such vaccination increases the liability to plague infection, and, by inducing fever and swollen glands, tends to confuse diagnosis at the port of arrival. This operation must be performed at the port of arrival, and just prior to release from quarantine.

Baggage labelled and sealed by the consul or medical officer of the Marine-Hospital Service at a non-infected city may be admitted without disinfection, even though shipped through an infected port or locality, provided it arrives with the seal unbroken. Such baggage should be accompanied by a certificate of origin and non-exposure to infection.

Passengers coming from an infected or suspected locality and desiring to take passage at a non-infected port should be held fifteen days under observation before being allowed to embark; otherwise the ship and all on board will be considered by the quarantine officer at the port of arrival in the United States as coming from an infected port. Any baggage from such infected or suspected localities destined for shipment through a non-infected port must be disinfected prior to shipment.

In a port where plague prevails, the vessel should not tie up to the dock. No lines should be passed to the shore that might permit rats on board. Passengers and cargo should be lightered; the crew not be allowed ashore, and personal communication from shore to vessel shall be under medical supervision. A statement to this effect from a medical officer of the Marine-Hospital Service will have weight with the quarantine officer at the port of arrival in determining the questions of disinfection and time of detention.

Mammalian animals, such as dogs, cats, monkeys, mice, etc., which not infrequently accompany passengers as pets, should not be shipped from a plague infected or suspected port or place.

THIRTEENTH INTERNATIONAL MEDICAL CONGRESS.

The Secretary-General of the Congress gives notice of the following reductions in rates:

(1) All the railway companies of France will grant to the members of the Congress a reduction of 50 per cent. upon round trip tickets as follows: Every member of the Congress will receive, upon application to the Secretary-General,[1] a ticket which must be stamped at the railroad station where he enters France, upon paying the full price of a single trip to Paris. At Paris the member will have this ticket viséd in the

[1] Dr. A. Chauffard, 21, Rue de l'École de Médecine, Paris.

office of the Congress, and it will then serve as a return ticket without additional expense. The journey to Paris having been paid entirely, and the return trip being free, there is of course a 50 per cent. reduction. It goes without saying that in order to secure this, the return trip must be to the same point at which the original fare was paid.

(2) The French Line (La Compagnie Générale Transatlantique) will allow members of the Congress a reduction of 10 per cent. on tickets from New York.

(3) The Secretary-General has arranged to provide to early applicants a number of lodgings, including light and service, at the rate of five francs per day; and various agencies also advertise reduced rates for lodgings.

For further particulars and application blanks for membership, address Dr. H. B. Jacobs, Secretary American National Committee, 3 W. Franklin St., Baltimore, Md.

ACTING ASSISTANT SURGEONS IN THE PHILIPPINES.

SURGEON-GENERAL STERNBERG, United States Army, writes us that the Medical Department of the Army is now in need of some additional assistance in the Philippines, and it is desired that candidates for appointment as acting assistant surgeons will make application to the Surgeon-General of the Army. Applicants must be graduates of reputable medical colleges, who have had practical experience, since graduation, in hospitals or in private practice. Candidates between the ages of twenty-five and thirty-five are preferred. Candidates should forward with their application one or more letters from well-known professional men, giving testimony as to their character and qualifications. Appointments will not be made through political influence, and letters designed to produce political effect will injure rather than benefit the applicant. All applicants will be examined as to their physical and professional qualifications for service in the Philippines before they are given a contract. Contracts are made for one year, with the understanding that the approved candidate will remain in service for a longer period if his services are required.

METEOROLOGICAL RECORD

For the week ending February 3d, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 2,677; under five years of age 903; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping-cough, erysipelas, fevers and consumption) 552, acute lung diseases 554, diphtheria and croup 124, scarlet fever 38, measles 33, typhoid fever 23, diarrheal diseases 18, erysipelas 16, whooping-cough 16, cerebrospinal meningitis 10.

From typhoid fever New York 13, Philadelphia 6, Boston and Baltimore 2 each. From diarrheal diseases New York 8, Philadelphia, Baltimore and Fall River 2 each, Providence, Lawrence, Springfield and Taunton 1 each. From erysipelas New York 9, Philadelphia 4, Boston, Baltimore and Worcester 1 each. From whooping-cough New York 11, Boston 3, Baltimore and Lowell 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending January 27th, the death-rate was 22.6. Deaths reported 5,025: acute diseases of the respiratory organs (London) 490, measles 123, whooping-cough 99, diphtheria 94, diarrhea 43, fever 35, scarlet fever 33, small-pox (Hull) 1.

The death-rates ranged from 8.9 in Cardiff to 30.7 in Preston: Birmingham 27.2, Bradford 24.9, Gateshead 26.7, Hull 28.0, Leeds 23.8, Liverpool 29.5, Manchester 23.8, Newcastle-on-Tyne 26.0, Nottingham 19.1, Sheffield 22.5, Swansea 15.3.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 10, 1900.

M. S. ELLIOTT, passed assistant surgeon, commissioned passed assistant surgeon from October 6, 1899.

J. A. HAWKE, medical director, commissioned medical director from September 24, 1899.

R. A. MARMION, medical director, commissioned medical director from October 23, 1899.

D. DICKINSON, medical director, commissioned medical director from November 11, 1899.

M. C. DRENNAN, medical director, commissioned medical director from February 5, 1900.

T. H. STREETS, medical inspector, commissioned medical inspector from April 16, 1899.

G. E. H. HARMON, medical inspector, commissioned medical inspector from November 11, 1899.

J. W. WAGGENER, medical inspector, commissioned medical inspector from February 8, 1899.

T. A. BERRYHILL, surgeon, commissioned surgeon from April 9, 1899.

E. P. STONE, surgeon, commissioned surgeon from April 16, 1899.

R. K. SMITH, passed assistant surgeon, commissioned passed assistant surgeon from April 3, 1899.

R. S. BLAKEMAN, passed assistant surgeon, commissioned passed as istant surgeon from May 27, 1899.

J. C. ROSENBLEUTH, passed assistant surgeon, commissioned passed assistant surgeon from October 14, 1899.

G. W. COSTIGAN, passed assistant surgeon, commissioned passed assistant surgeon from February 8, 1900.

G. H. BARBER, passed assistant surgeon, detached from the Naval Academy, February 10th, and ordered home and to be ready for orders to sea duty.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING FEBRUARY 8, 1900.

WASDIN, EUGENE, surgeon. On expiration of leave of absence to proceed to New York, N. Y., for orders. February 5, 1900.

WERTENBAKER, C. P., passed assistant surgeon. To proceed to Martinsville, Va., for special temporary duty. February 7, 1900.

AMESSE, J. W., assistant surgeon. To proceed to Cleveland, O., for temporary duty during the absence of Surgeon W. J. PETTUS. February 6, 1900.

GIBSON, R. H., hospital steward. Relieved from duty at South Atlantic Quarantine Station, and directed to proceed to Gulf Quarantine Station, Miss., for duty and assignment to quarters. February 2, 1900.

O'GORMAN, T. V., hospital steward. Relieved from duty at Gulf Quarant ne Station, and directed to proceed to Louisville, Ky., for duty and assignment to quarters. February 2, 1900.

MCKAY, N., hospital steward. Granted leave of absence for five days from January 29th. February 2, 1900.

COMFORT, N. C., hospital steward. To report at Washington, D. C., for special temporary duty. February 2, 1900. To proceed to Manila, P. I., and report to Passed Assistant Surgeon J. C. PERRY, chief quarantine officer, for duty. February 7, 1900.

SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The Section for Clinical Medicine, Pathology and Hygiene will hold its meeting at 19 Boylston Place, Wednesday, February 21, 1900, at 8 P. M.

At 8 o'clock: Dr. J. L. Morse will report "An Analysis of Fifty-one Cases of Pneumothorax."

At 8 20 o'clock: Dr. R. W. Greenleaf will read a paper (postponed from the December meeting) entitled, "The Psychic Factor in Disease." The discussion will be opened by Dr. E. W. Taylor.

J. BERGEN OGDEN, M.D., *Secretary*,
Harvard Medical School, Boston.

AMERICAN MEDICO-PSYCHOLOGICAL ASSOCIATION. — The meeting of the Association in Richmond, Va., will be held May 8th, 9th, 10th, 11th, not May 1st, 2d, 3d, 4th, as heretofore announced. The change in date is made to enable members to attend the Congress of American Physicians and Surgeons in Washington, May 1st-4th.

By order of the Council,

C. B. BURR, M.D., *Secretary*.

RECENT DEATHS.

WILLIAM V. RIGHTMORE, M.D., of Brooklyn, N. Y., died February 4th, at the age of thirty-six. He was a graduate of the Medical Department of the University of the City of New York in 1884.

T. DANA FITZSIMMONS, M.D., of Brooklyn, N. Y., a graduate of the Long Island College Hospital, died on February 5th, aged twenty-five years.

WILLIAM CARSEN, M.D., aged eighty-five, one of the oldest physicians in New Orleans, is dead. He was a native of Ireland and a graduate of the Royal College of Surgeons in London.

A. J. BILLINGS, M.D., of Freedom, Me., died February 7th, at Belfast. He was seventy-four years of age, and had been active in public affairs for many years. He was State senator in 1866 and in 1897, and had served two terms as representative. He was a member of the Waldo County Medical Society and served in the Civil War.

F. H. PETTINGILL, M.D., of Saxton's River, Vt., died last week. He was born in Grafton, attended Middlebury College, served in the Civil War, studied medicine at the University of Vermont, after the war, graduating from the Harvard Medical School in 1868.

A Text-Book of Diseases of Women. By Charles B. Penrose, M.D., Ph.D., Professor of Gynecology in University of Pennsylvania. Illustrated, third edition, revised. Philadelphia: W. B. Saunders. 1900.

The Climate of Colorado for Respiratory Diseases. The Tuberculin Test, and the Need of a More Complete Diagnosis of Tuberculosis. By Charles Denison, A.M., M.D., Denver, Colo. Reprints. 1898-1900.

Imperative Surgery, for the General Practitioner, the Specialist and the Recent Graduate. By Howard Lilenthal, M.D. Illustrated. New York: The Macmillan Co. London: Macmillan & Co., Ltd. 1900.

The Municipal Control of Prostitution in the United States: Some Opinions as to Methods Adapted to Municipal Care and Control of Prostitution and Venereal Diseases. By Isadore Dyer, Ph.B. (Yale), M.D. Reprint. 1899.

Report on Observations made upon the Cattle at the Experimental Station at Outremont, P. Q., Recognized to be Tuberculous by the Tuberculin Test. By Prof. J. George Adami, M.A., M.D., and C. F. Martin, M.D. Ottawa. 1899.

A Text-Book of Embryology for Students of Medicine. By John Clement Heisler, M.D., Professor of Anatomy in the Medico-Chirurgical College. Philadelphia. With 190 illustrations, 26 of them in colors. Philadelphia: W. B. Saunders. 1899.

Manuel Pratique d'Hygiène à l'Usage des Médecins et des Etudiants. Par le Dr. Guiraud, Professeur d'Hygiène à la Faculté de Médecine de l'Université de Toulouse. Deuxième édition, revue et augmentée. Paris: G. Steinheil, Editeur. 1899.

Recherches sur les Matières Colorantes du Foie et de la Bile et sur le Fer Hépatique. Par MM. A. Dastre, Professeur de Physiologie a la Faculté des Sciences de Paris, et N. Floresco, Docteur ès-Sciences. Paris: G. Steinheil, Éditeur. 1899.

The American Year-Book of Medicine and Surgery: being a Yearly Digest of Scientific Progress and Authoritative Opinion in all Branches of Medicine and Surgery. By George M. Gould, M.D. In two volumes. Philadelphia: W. B. Saunders. 1900.

The Refraction of the Eye, including a Complete Treatise on Ophthalmometry, a Clinical Text-Book for Students and Practitioners. By A. Edward Davis, A.M., M.D. Illustrated. New York: The Macmillan Co. London: Macmillan & Co., Ltd. 1900.

The Treatment of Diseases of the Nervous System, a Manual for Practitioners. By Joseph Collins, M.D., Professor of Nervous and Mental Diseases in the New York Post-Graduate Medical School, etc. Illustrated. New York: William Wood & Co. 1900.

Pyorrhœa Alveolaris and its Relations to General Medicine. By John Fitzgerald, L.D.S., Dental Surgeon to the Italian Hospital and to the National Hospital for Diseases of the Heart and Paralysis, Soho Square. London: The Medical Publishing Co., Ltd. 1899.

Enlargement of the Prostate: Its Treatment and Radical Cure. By C. Mansell Moullin, M.D. (Oxon.), F.R.C.S., Surgeon and Lecturer on Surgery at the London Hospital, etc. Second edition. London: H. K. Lewis. Philadelphia: P. Blakiston's Son & Co. 1899.

Herman Ludwig Ferdinand von Helmholtz. By John Gray McKendrick, M.D., LL.D., F.R.S.S.L. and E., Professor of Physiology in the University of Glasgow and Fellow of the Royal College of Physicians of Edinburgh. New York: Longmans, Green & Co. 1899.

Diseases of Women: A Treatise on the Principles and Practice of Gynecology for Students and Practitioners. By E. C. Dudley, A.M., M.D., Professor of Gynecology, etc. Second edition, revised and enlarged. Illustrated. Philadelphia and New York: Lea Brothers & Co.

The Diseases of Children, Medical and Surgical. By Henry Ashby, M.D. (Lond.), F.R.C.P., and G. A. Wright, B.A., M.B. (Oxon.), F.R.C.S. (Eng.). Fourth edition, edited for American students by William Perry Northrup, A.M., M.D. London and Bombay: Longmans, Green & Co. 1900.

Manual of Clinical Chemistry. By Elias H. Bartley, B.S., M.D., Ph.G., Professor of Chemistry and Toxicology in the Long Island College Hospital; Dean and Professor of Organic Chemistry in the Brooklyn College of Pharmacy. Thirty-three illustrations. Philadelphia: P. Blakiston's Son & Co. 1899.

Raynaud's Disease (Local Syncope, Local Asphyxia, Symmetrical Gangrene), Its History, Causes, Symptoms, Morbid Relations, Pathology and Treatment. By Thomas Kirkpatrick Monro, M.A., M.D., Physician to the Glasgow Royal Infirmary; Examiner in the University of Glasgow. Glasgow: James Maclehose & Sons. 1899.

A Manual of Modern Surgery: An Exposition of the Accepted Doctrines and Approved Operative Procedures of the Present Time for the use of Students and Practitioners. By John B. Roberts, A.M., M.D., Professor of Anatomy and Surgery, etc. Second edition, revised and enlarged. Illustrated. Philadelphia and New York: Lea Brothers & Co.

Lea's Series of Pocket Text-Books. Practice of Medicine: A Manual for Students and Practitioners. By George E. Malsbary, M.D., Assistant to the Chair of Practice, Medical College of Ohio, University of Cincinnati, etc. Series edited by Bern B. Gallaudet, M.D. Illustrated with 45 engravings. Philadelphia and New York: Lea Brothers & Co. 1899.

A Compend of the Diseases of the Eye and Refraction, including Treatment and Surgery. By George M. Gould, A.M., M.D., formerly Ophthalmologist to the Philadelphia Hospital, etc., and Walter L. Pyle, A.M., M.D., Assistant Surgeon to Wills Eye Hospital, Philadelphia, etc. Second edition, revised and enlarged. Philadelphia: P. Blakiston's Son & Co. 1899.

Saunders' Question Compends, No. 3. Essentials of Anatomy, including the Anatomy of the Viscera arranged in the Form of Questions and Answers, prepared especially for Students of Medicine. By Charles B. Nancrede, M.D. Sixth edition, thoroughly revised by Fred J. Brockway, M.D., Assistant Demonstrator of Anatomy, Columbia University, New York. Philadelphia: W. B. Saunders. 1899.

The Treatment of Wounds, Its Principles and Practice, General and Special. By Lewis Stephen Pilcher, A.M., M.D., Surgeon to the Methodist Episcopal Hospital in New York; late Passed Assistant Surgeon, U. S. Navy; Fellow of the American Surgical Association; Member of the Brooklyn Surgical Society; Honorary Member of the New York Surgical Society. With 142 wood engravings. New York: William Wood & Co. 1898.

A Manual of the Practice of Medicine, prepared especially for Students. By A. A. Stevens, A.M., M.D., Professor of Pathology in the Woman's Medical College of Pennsylvania; Lecturer on Terminology and Instructor in Physical Diagnosis in University of Pennsylvania, etc. Fifth edition, revised and enlarged. Illustrated. Philadelphia: W. B. Saunders. 1899.

Lea's Series of Pocket Text-Books. Materia Medica, Therapeutics, Medical Pharmacy, Prescription Writing and Medical Latin, a Manual for Students and Practitioners. By William Schleif, Ph.G., M.D., Instructor in Pharmacy in the University of Pennsylvania. Series edited by Bern B. Gallaudet, M.D., Demonstrator of Anatomy and Instructor in Surgery, College of Physicians and Surgeons, New York, etc. Philadelphia and New York: Lea Brothers & Co. 1899.

Lea's Series of Pocket Text-Books. Diseases of Children: a Manual for Students and Practitioners. By George M. Tuttle, M.D., Attending Physician to St. Luke's Hospital, etc., St. Louis. Series edited by Bern B. Gallaudet, M.D., Demonstrator of Anatomy and Instructor in Surgery, College of Physicians and Surgeons, Columbia University, New York, etc. Illustrated with five plates in color and monochrome. Philadelphia and New York: Lea Brothers & Co. 1899.

Saunders' Pocket Medical Formulary, with an Appendix containing Posological Table; Formulæ and Doses for Hypodermic Medication; Poisons and their Antidotes; Diameters of the Female Pelvis and Fœtal Head; Obstetrical Table; Diet List for Various Diseases; Materials and Drugs used in Antiseptic Surgery, etc. By William M. Powell, M.D., author of "Essentials of Diseases of Children," etc. Fifth edition, thoroughly revised. Philadelphia: W. B. Saunders. 1899.

Text-Book of the Embryology of Invertebrates. By Dr. E. Korschelt, Professor of Zoölogy and Comparative Anatomy in the University of Marburg, and Dr. K. Heider, Professor of Zoölogy in the University of Berlin. Translated from the German by Matilda Bernard. Revised and edited with additional notes by Martin F. Woodward, Demonstrator of Zoölogy, Royal College of Science. Vols. II and III. London: Swan, Sonnenschein & Co., Ltd. New York: The Macmillan Co. 1899.

The Mineral Waters of the United States and their Therapeutic Uses, with an account of the Various Mineral Spring Localities, their Advantages as Health Resorts, Means of Access, etc., to which is added an Appendix on Potable Waters. By James K. Crook, A.M., M.D., Adjunct Professor of Clinical Medicine and Physical Diagnosis at the New York Post-Graduate Medical School; Attending Physician to the Post-Graduate Hospital, etc. New York and Philadelphia: Lea Brothers & Co. 1898.

Histology and Pathology, a Manual for Students and Practitioners. By John Benjamin Nichols, M.D., Demonstrator of Histology, Medical Department, Columbian University, Washington, D. C., and Frank Palmer Vale, M.D., Assistant in Pathology, University of Georgetown, Washington, D. C. Series edited by Bern B. Gallaudet, M.D., Demonstrator of Anatomy and Instructor in Surgery, College of Physicians and Surgeons, New York, etc. Illustrated. Philadelphia and New York: Lea Brothers & Co.

Holden's Human Osteology, comprising a Description of the Bones, with Delineations of the Attachments of the Muscles, the General and Microscopic Structure of Bone and its Development. Edited by Charles Stewart, F.R.S., Conservator of the Museum of the Royal College of Surgeons of England; Hunterian Professor of Comparative Anatomy and Physiology, Royal College of Surgeons of England, and R. THE UNITY OF THE ACUTE PSYCHOSES.[1]

BY PHILIP COOMBS KNAPP, A.M., M.D., BOSTON,
Clinical Instructor in Diseases of the Nervous System, Harvard Medical School; Physician for Diseases of the Nervous System, Boston City Hospital.

Some years ago I was called to see a young woman who had had a sudden nervous collapse one morning after breakfast. The history was unfortunately only too common. She had always been in delicate health. The family history showed some slight neurotic tendencies. She herself had had lateral curvature of the spine, slight in degree, and not important except that it had been made the occasion for exhausting treatment. She was possessed of the New England conscience to a high degree, unsanctified by a keen sense of humor or the power of relaxation. For a number of years there had been a source of worry in her family life, and she had been studying hard, working late at night, neglecting her meals, and hurrying from one end of the town to the other to attend lectures, concerts or operas, or to study in the libraries. A slight uterine disturbance had led to needless gynecological interference, which had had a bad effect upon her morbid conscientiousness. As a result of it all she had become very nervous and sleepless and had suffered much from intense pain in the head and spine. A change was advised, but scarcely had she started on her travels when she collapsed. This was followed by a long period of exhaustion and a gradual restoration to health. For a considerable period she had been brought in contact with a member of her family who had presented certain nervous phenomena, which had not been understood by the family physician, and thus she had been led to dread for herself an attack of insanity, so that she had implored her family never to send her away to an asylum. In addition, she had become profoundly depressed, and had the dominant idea of suicide, which, to a person of her morbid conscientiousness, seemed a horrible sin. At times she had sat sad and motionless, refusing to speak or even to look at any one, answering in monosyllables only after a direct question had been put to her several times. With all this there were no delusions, no hallucinations, no mental impairment, no confusion, except for an hour or two one night just after her collapse, when she struggled silently to get out of bed during a period of intense headache.

I have briefly outlined the case, not because it is in any way remarkable or because it presents any special difficulties or obscurities, but simply because it serves to introduce a question in the way of diagnosis. Is it a case of neurasthenia or of melancholia? She was both neurasthenic and melancholy, but was the melancholy sufficient to warrant the diagnosis of acute melancholia, or was it merely the melancholy which so often accompanies neurasthenia? Such profound depression is, of course, rare in neurasthenia, but more than half the neurasthenics complain of depression, and very few are persistently cheerful. It would be tedious to rehearse cases to show that in neurasthenia we may have all degrees of depression, until we find it as pronounced as in this patient. That is a fact which every neurologist knows from his own experience. The only question is at what point to draw the line between the two. Having drawn the line, moreover, we must recognize all sorts of gradations in the degree of depression, blending almost imperceptibly into one another. The extremes may be clearly differentiated, but in this case, as in so many others, the line of demarcation is not sharp.

Whether this be melancholia or neurasthenia, however, we must admit that there are other cases of mental depression which differ markedly in their clinical aspect from this. I need not cite now illustrative cases of melancholia with stupor, where there are marked mental confusion, hallucinations, and mental impairment, with a comparatively sudden onset, and without so many profound neurasthenic symptoms; nor need I cite any illustrative cases of melancholia with systematized delusions, chronic course, active hallucinations, and slight mental impairment. Both types are familiar, and they differ fundamentally from the case I have already referred to. This case, as I have said, bears a close resemblance to cases of neurasthenia, while melancholia with systematized delusions bears an equally close relation to paranoia, and the melancholia with stupor stands in a third class, differing markedly from the other two. Are these three types one and the same disease, characterized by the affective state depression, or is depression merely a symptom, occurring in a variety of diseases? The latter seems the more rational answer. Melancholy is an affective state, which is the normal result of certain conditions. If a man knows that he is suffering from an incurable disease, that he has lost his property, that he has incurred disgrace, that he has lost those near and dear to him, he becomes naturally and inevitably depressed. If, owing to false information, he believes that these things have happened, he becomes equally depressed. If, owing to insane delusions, he believes that these things have happened, he still becomes equally depressed. The affective state is the result of certain pre-existing ideas; it is not necessarily a disease by itself.

The same may be said of the states of excitement so often seen. In many cases they are but the natural actions of the patient produced by his morbid ideas or delusions. If a man be exposed to imminent danger, he will assault the man who prevents his escape; if he be a king, he will punish the man who does not pay him due deference; he will behave in the same manner if he believes these things, even if his beliefs be unfounded or part of an insane delusion. There is much truth in Alt's recent assertion[2] that violent mania is an artefact, due to psychical sepsis in the hospital; that is, to defective management and unskilful treatment.

The idea that melancholia, one of the oldest recognized types of mental disease, which in the days of Robert Burton was regarded as one of the commonest and most universal forms of disease, is not a pathological entity, but an affective state occurring in several forms of disease, indicates something of the revolution that is taking place and the confusion that exists in our conceptions of mental disease. Mania, that other time-honored type, occupies a still more uncertain place. In spite of the frequency with which mania is diagnosticated in this country, as shown by asylum statistics, a large number of modern writers regard it as rare, and many question its existence. A similar contest is going on with regard to katatonia, whether

[1] Read before the American Neurological Association, June, 1899.

[2] Monatsschrift für Psychiatrie, June, 1897.

it is a disease by itself or merely a symptom complex. One school vigorously upholds the existence of an acute paranoia, whose existence is denied by another school. In the whole field of the acute psychoses there is questioning and uncertainty. If we compare the modern treatises on mental disease, excluding of course those which are merely imitations of some original writer's work, we will find that no two of them agree in the diseases which they describe.[3] Each writer has his own list of diseases which he differentiates carefully from one another, and this list differs absolutely from the lists of other writers; but in no treatise on insanity are the distinguishing points as distinctive as could be desired, and nearly every writer admits that certain of his distinctive affections may sometimes be confounded.

This confusion is the natural result of the attempt to divide mental affections upon a symptomatic basis. Such a classification is, in certain states of our knowledge, inevitable, but eventually it must go the way of the etiological classifications. Even in diseases with definite physical symptoms such classifications are often misleading. Any man who has seen a dozen cases of brain tumor or tabes could divide them into several distinct types, if he were to classify according to their most striking symptoms. Of the three cardinal symptoms of tabes — lancinating pains, loss of knee-jerk and Argyll-Robertson pupil — only one is complained of by the patient, and the other two can be detected only by expert examination. Ataxia, gastric crises, blindness, joint affections, which may dominate the clinical picture, may all be absent. In the one form of mental disease, concerning which there is general agreement and which is described in substantially the same way and under the same name by every author, namely, general paralysis, — the clinical symptoms may vary widely, and, were we to classify by these alone, every man could describe a dozen different types from his own case books. If so many types may be distinguished when the symptoms are chiefly physical, may not as many and as unwarranted types be created when the symptoms are of a complex psychical nature? The appalling list of the phobias shows the possibilities and the evil of such classification.

This fallacy has been well brought out by Kraepelin in his criticism of the attempt to establish an acute paranoia, and especially of Ziehen's distinction between the simple and the hallucinatory forms. "In this," he says,[4] "we meet with the plainest indication of the essential failure of our clinical psychiatry in the last decade, the purely symptomatic division of forms of disease resting upon *a priori* presumptions. The distinction which is regarded as fundamental between the disturbances of intellect and those of feeling is only psychological, not at all clinical. In actual disease types we see both tied up together in a wholly indistinguishable way. If this be not plain, try to group cases universally recognized as general paralysis according to the primary or secondary development of delusions. This plain example, from which the clinical comprehension of psychical disturbances will never learn anything, shows more than sufficiently that delusions and hallucinations are as inessential for the characterization of a clinical type as the appearance of depression or excitement. . . . In fact, the attempt thus far made to arrange the paranoia group by itself and separate it from other forms of insanity has invariably ended with the confession that mixed forms and transition forms predominate over the regular forms themselves and even run into the affective mental disturbances which are supposed to be essentially different. Thus the only basis of the present conception of paranoia, the artificial distinction between diseases of the intellect and diseases of the affective sphere, falls to pieces. There is no doubt that the hopelessness of coming to any clear conclusions in this way must bear a great part of the blame for the general repugnance toward the study of clinical psychiatric questions." A sound criticism, which Kraepelin himself has unfortunately not followed. General paralysis itself may present every important symptom in the entire list of psychiatric semeiology, depression, excitement, confusion, delusions, hallucinations, dementia.

The almost hopeless confusion which the effort to reconcile various opinions in regard to the so-called acute psychoses produces may naturally lead us to consider, if not to take refuge, in alcohol. The pathological changes produced in the cortical nerve cells by alcohol have, of late years, been carefully studied, and it is recognized that alcoholic poisoning causes degenerative changes in the cortical cell. In acute alcoholic poisoning, however, in the "simple drunk," we are familiar with various mental states. The intoxicated man may be verbose, jocose, lachrymose, morose, bellicose, or comatose. The mental conditions due to chronic alcoholic poisoning are also of various types. One of the most familiar forms is, of course, the ordinary delirium tremens, — an acute hallucinatory delirium with ideas of persecution, of short duration and often terminating fatally; a condition which, clinically, is not unlike acute delirium.

A short time ago I saw on the same day two patients who presented two other familiar types of mental disturbance due to alcohol. One was a young man of thirty-two who, for ten or twelve years, had indulged in alcohol to excess. The family history and previous history were not remarkable. Three months

[3] I have cited from a few writers the various affections they describe which might fairly be classed among the acute psychoses. Ballet and Meynert do not give any complete classification. The various types are described under sixty-six different names:

Clouston: Simple melancholia, hypochondriacal melancholia, delusional melancholia, excited melancholia, resistive melancholia, convulsive melancholia, organic melancholia, suicidal and homicidal melancholia, simple mania, acute mania, delusional mania, ephemeral mania, homicidal mania, katatonia, melancholia attonita, primary dementia, 16.

Bevan Lewis: Depression, stupor, exaltation, fulminating psychoses, alcoholic insanity, insanity of puberty and adolescence, puerperal insanity, confusional insanity, climacteric insanity, 9.

Spitzka: Mania, melancholia, katatonia, transitory frenzy, stuporous insanity, primary confusional insanity, delirium grave, alcoholic insanity, 8.

Ballet: Mania, melancholia, confusion, acute delirium, 4.

Korkhoff: Melancholia, mania, acute paranoia, confusion, primary dementia, toxic insanity, 6.

Kraepelin: Collapse delirium, acute confusion, acute dementia, febrile delirium, toxic delirium, dementia præcox, katatonia, dementia paranoides, melancholia, 9.

Krafft-Ebing: Melancholia, passive melancholia, melancholia attonita, mania, frenzy, stupidity, 6.

Meynert: Melancholia, amentia, mania, 3.

Schüle: Melancholia, mania, severe mania, acute dementia, insanity of severe disease or intoxication, acute delirium, 6.

Ziehen: Mania, melancholia, stupidity, acute hallucinatory paranoia, acute simple paranoia, post-maniacal and post-melancholy stupor, post-neurasthenic hypochondriacal melancholia and paranoia, post-melancholic hypochondriacal paranoia, katatonia, alcoholic dementia, 12.

Apostoli: Mania, simple melancholia with delirium, agitated melancholia, melancholia attonita, confusional amentia, stuporous amentia, acute delirium, syphilitic psychoses, pellagrous psychoses, alcoholic psychoses, morphinism, etc., katatonia, 13.

Morselli: Hebephrenia, climacteric insanity, simple mania, grave mania, simple melancholia, grave melancholia, stupidity, katatonia, acute delirium, toxic insanities, 10.

International: Acute mania, puerperal mania, acute melancholia, puerperal melancholia, primary dementia, toxic insanity, 6.

[4] Kraepelin: Psychiatrie, 5te Aufl., p. 655.

before he had had a light attack of "the horrors," lasting about a week; since that time he had had the delusion that his enemies were influencing him with an electric machine; that he could hear them talking about him, threatening to arrest and kill him. They knew his thoughts and everything which he did. Certain muscular twitchings, due perhaps to a very slight neuritis, were interpreted as taps from the electric influences; after which he heard his own name and the names of his enemies spoken. His enemies repeated everything he thought and told him they would kill him with electricity. Their suggestions were often indecent. He never had any hallucinations of sight. At times he recognized the voices as false, but more frequently they were real. In consequence of his persecutions he was depressed, irritable and unable to keep his mind upon his business, but there was no failure of memory or judgment, no confusion and no other mental impairment. After three weeks of total abstinence the delusions and hallucinations were much diminished.

On the same day I saw a woman of forty-four, possibly approaching the menopause, who had indulged very freely in alcohol. For three weeks she had had some bronchitis, with digestive disturbance and elevation of temperature, for which she entered the hospital. She was found to be very weak and tremulous and somewhat delirious, getting out of bed frequently at night, but never becoming especially violent. On account of her getting out of bed, restraint became necessary. On examination she was found to have a moderate degree of neuritis and to show very marked mental confusion and loss of memory. She gave the characteristic account of having made several visits to her friends outside during her two weeks' stay in the hospital, with circumstantial statements as to the events which had happened during those visits. There was much confusion as to dates and much of the time she was not certain where she was. After total abstinence from alcohol she improved so much that in the course of a month she was able to return to her friends.

In yet a fourth type, which is seen only in more advanced cases, there is still more marked dementia, great muscular weakness, more marked loss of memory and confusion, disturbances of speech and occasional convulsions, the whole suggesting general paralysis. The course is protracted, the prognosis grave and complete recovery is rare. In this last form we find edema and opacity of the pia, atrophy of the cortex and more marked atrophic changes in the cells and in the glia, the familiar "wet brain" of chronic alcoholism. Other forms might be described, and mixed and transition types exist.

In all these types of mental disturbance, — which clinically are distinct, if we disregard the transition forms, which spoil our classifications, — the etiology is the same, the anatomical changes differ only in degree, but the clinical aspect is widely different. Is it not fair to suppose, therefore, that the difference in the symptoms is due to the difference in the extent of the cortical changes or perhaps to a difference in their localization? In other diseases of the brain — hemorrhage, abscess, tumor — we know that the extent and location of the lesion are of much greater importance than the etiology or the precise anatomical nature. Is it not also probable that the different manifestations in general paralysis are dependent upon the extent and localization of the changes in the cortex, excepting, of course, those manifestations clearly referable to changes in the spinal cord? The paralyses and convulsions of general paralysis are probably to be referred to local changes, and although we cannot as yet accept Flechsig's speculation[2] that disturbances of personality are due to changes in the anterior association centre, the clinical differences in the mental symptoms of general paralysis are more satisfactorily explained by differences in the part of the cortex affected and by differences in the extent of the degeneration than by any other causes. At any rate, both in alcoholism and in general paralysis it seems safe to claim that the degree of the dementia is dependent upon the number of cortical neurones that are put out of function; the rapidity with which the dementia develops depends upon the rapidity with which these neurones are affected by the morbid process; and the permanence of the dementia depends upon whether the neurones are wholly destroyed or are capable of repair. The study of the pathological changes in the cortex in the early and late stages of general paralysis establishes this point beyond dispute.

Let us now consider for a few moments the so-called acute psychoses. What they are it is hard to say, since, as I have said, the list varies with each treatise on psychiatry consulted. They would include, however, many of the cases now classed as acute mania, acute melancholia, acute dementia, dementia precox, katatonia, acute delirium, acute paranoia and acute confusional insanity. The pathology of these conditions is defective, and any satisfactory pathology in mental disturbances is at present wholly impossible, yet, in a few instances, an acute degeneration of the cortical neurones, occasionally in the severer cases associated with proliferation of the glia, has been found. These changes are not unlike those produced by certain poisons, such as alcohol, or those produced as a result of acute infectious processes. In fact, it is generally admitted that, with our present methods of research, it is impossible to detect from the anatomical differences in the affected cortical cells whether the degeneration be due to alcohol, other poisons, acute infection or acute mental disease.

Clinically, these psychoses resemble each other in that they often seem to be produced by toxic causes, that they may affect the healthy brain, that they are of comparatively rapid onset and that they may run a tolerably acute course. Furthermore, one cause may produce several different clinical types of psychosis. I have already referred to some of the varying conditions, with probably a similar pathological basis, produced by alcohol — acute delirium, acute delusional insanity, an acute confusional condition, and a more marked and more chronic form of dementia. As a result of child-bearing, or more probably of the acute infection associated with the puerperal state, we see various types of puerperal psychosis — mania, melancholia, and the acute hallucinatory confusional insanity so often confounded with mania. Manifestations of febrile delirium, when not associated, as it so often is, with alcoholic poisoning, show a similar variety in the mental symptoms. All these psychoses, moreover, show certain likenesses in their course; they may vary, of course, in severity, but we must admit that in all the so-called types of mental disease to which I have referred, even in katatonia and acute delirium,

[2] Flechsig: Gehirn und Seele, 2te Aufl, p. 90.

recovery is possible. The cases which do not recover, however, either die of exhaustion, after a comparatively short illness, or they end in one of two ways — they either pass on to a more or less marked dementia or to a state associated with hallucinations and not very well systematized delusions, with considerable mental impairment. We may explain the course by imagining that the cell degeneration has in some cases been slight, and that a process of repair has followed, leading to a complete recovery. In other cases there may have been a sudden and widespread degeneration of many cortical cells, causing death; or there may have been a more complete degeneration of a greater or smaller number of cells, from which repair was impossible; and in case of the destruction of these cells, either mental impairment with delusions or a more complete dementia would be the inevitable result.

Many of these cases, if studied throughout their course, present various changes in their psychical manifestations. The old descriptions of mania and melancholia used to tell of the stages of depression or exaltation, respectively, preceding or following the period of excitement or depression that gave the name to the disease. This description may have been founded upon the cases of unrecognized circular insanity, but the fact remains that in so-called mania and melancholia, as well as in other affections, we may have various changes in the clinical picture —what Ziehen calls the polymorphous psychoses [6] which often present a course beginning with depression, going on to excitement, then confusion, and finally dementia. Other cases may begin with vague delusions of persecution and hallucinations, which may be permanent or go on to more marked confusion and considerable dementia, and yet make a good recovery. Often the depression or excitement is merely a secondary condition, the consequence of delusions, fancied ill-treatment, the bad effects of environment in the violent ward of an asylum, and the like. In a very large number of cases of acute psychoses recent studies have shown the existence of marked mental confusion, going on to stupor. Meynert's exhaustive study of acute hallucinatory insanity — amentia [7] — has caused an increasing tendency to put many cases under this one heading. It has absorbed many of the cases of acute mania, now regarded as a rare disease, it has taken in a few cases of melancholia, many of the cases of acute dementia and many of the cases of acute paranoia. Wernicke [8] has recently admitted frankly that the majority of the acute psychoses should be classed under this head.

The conclusions to which these various facts tend is that in these acute psychoses we have to do, not with a variety of different diseases, but, after all, with one single affection, whose anatomical basis may be an acute degeneration of the cortical neurones, and — if we adopt Wernicke's suggestion [9] (which seems to me the most sound one) that insanity is a disease of the association system — a degeneration which causes a greater loss of function in the association neurones of the cortex than in the neurones which belong to the projection system. This affection may vary in its severity and in its clinical manifestations. It is most frequently due to some toxic process (such as alcohol, post-infectious toxins, or perhaps autotoxins), or to exhaustion (toxins of fatigue). It is often attended at the onset with some febrile disturbance; a slight rise is not uncommon in milder cases, and a marked rise is the rule in delirium grave. Under certain conditions (perhaps a marked virulence or a very large dose of the poison) the symptoms are of sudden onset, with states of active delirium which may speedily cause death by exhaustion. Under ordinary conditions, states of confusion or hallucinatory delusion are produced, which may remain through the course of the disease or which may go on more or less rapidly to dementia. If the changes be not too complete and too extensive, recovery may ensue, or, in some cases, recovery with some persistent mental defect. The variation in the clinical picture is due to the varying extent and severity of the morbid changes or perhaps to a varying localization.

Two other factors may modify the picture. The first is the period of life, about which has been much written, chiefly with the end of establishing new diseases, such as hebephrenia or climacteric insanity. The other is degeneracy. That acute psychoses may occur in the degenerate is obvious, but little has been done toward the study of the question how far degeneracy may modify the symptoms of a psychosis. Agostini [10] is the only writer I recall who devotes a special chapter to the subject, based upon the researches of Magnan and Morselli. This is not surprising, for, with the confusion that prevails in the whole domain of the acute psychoses, any, even a slight, modification of the clinical type would probably be raised to the rank of an independent disease.

The periodic and circular forms of insanity add some support to the hypothesis advanced above. We may have a recurrence of the same clinical type — mania, melancholia, acute hallucinatory paranoia, acute simple paranoia — or we may have recurrence of different clinical types, usually mania and melancholia, but sometimes confusion or dementia. When the recurrence is in double form the two types do not necessarily alternate; there may be several attacks of excitement and then an attack of depression, as have been shown by some very interesting charts by Magnan [11] and confirmed by Ballet.[12] Of the pathogenesis of the periodic and circular forms of insanity we know nothing. If, however, the attacks be due to some agency of slow development, leading ultimately to an explosion, analogous to the epileptic attack, the same cause may produce excitement, confusion or hallucinatory delusions, according to the extent or location of the morbid changes.

Following out the hypothesis here advanced and returning to the case cited at the beginning of this paper, it seems justifiable to regard it as one of neurasthenia with marked depression; chronic delusional melancholia may be classed as paranoia, and melancholia with stupor as but one manifestation of this acute psychosis. Melancholia thus vanishes from our list of diseases, but the symptom melancholy remains, occurring in many affections and from varying causes, but secondary to pre-existing delusions or morbid ideas.

That such an hypothesis should be accepted, however, is hardly to be expected. That the etiological

[12] Traité de Médecine, vi, 1124.

factors may vary, giving rise to variations in the clinical type, is possible, but an etiological classification can hardly be sustained at the present time. Multiple neuritis, for example, may rise from many different causes — lead, alcohol or diphtheria — and the clinical differences between lead neuritis, alcoholic neuritis, and diphtheritic neuritis are more striking than between Kraepelin's amentia and his acute dementia, or between Ziehen's acute hallucinatory and acute simple paranoia; yet we recognize practically one morbid anatomical change as the basis of the symptoms in all the different forms of neuritis, varying in extent and distribution and varying in severity. Clinically, of course, the acute psychoses may vary markedly; the typical cases of mania, hallucinatory confusion and dementia precox are strikingly different; but there are many transitional forms, so that a sharp line of demarcation between them does not exist. Clinically there is a striking contrast between the mute, drooling patient with bulbar paralysis, the upper face sad and intelligent the lower face expressionless and imbecile, and the loquacious patient with wasted, flail-like arms of ordinary, progressive muscular atrophy; yet most neurologists now regard the two as manifestations of the same morbid process, differing only in the localization of the lesion. We can hardly distinguish moreover by the clinical course of the disease; many of these patients, we know, become rapidly demented, others recover completely; some die of exhaustion, others remain hopelessly insane, victims of marked delusions, yet not markedly demented. A similar distinction can be made with other diseases. Some diphtheria patients hardly seem sick, some die of suffocation, others die of vagus paralysis, others recover, apparently, to suffer later from paralysis of the pharynx, eyes and limbs.

It is therefore no argument against regarding the acute psychoses as one affection to say that the causes vary; that some get well, others die of exhaustion, others become chronically insane, and others become demented; that individual cases differ clinically, some being excited, others depressed, others filled with delusions, and others demented; or to argue that cases presenting certain symptoms turn out worse than others which present other symptoms, just as diphtheria with laryngeal symptoms is more fatal than diphtheria without. All these conditions may be of service in establishing different diseases, but they are all of uncertain value and they may be fallacious. The trend of opinion during the last decade seems to be more and more in the direction of regarding the acute psychoses as one. Mania and melancholia still keep their old-time position in the text-books, but the very existence of mania is threatened and its rarity generally admitted, except in those hospital reports which find one case of paranoia and ten general paralytics in 4,000 admissions. Meynert's amentia is assuming more and more the chief place among the acute psychoses. The hypothesis of the essential unity of the various psychoses on a pathological basis of acute degenerative changes in the cortical cells seems the most plausible solution of the many difficulties and obscurities that enwrap the question, a solution which I believe will be strengthened by further study.

This hypothetical pathology affords, also, certain useful suggestions in the way of treatment. If the disorder be due to acute degenerative changes in the cortical neurones, the treatment would naturally be similar to that of other inflammatory disturbances in the brain — absolute rest, physical and mental, absence of noise, bright light and other mental stimuli, abundant feeding of not too stimulating a type, free elimination by the bowels and kidneys, and possibly in the more intense cases of toxic origin, bleeding, followed by saline injections. The benefits of the "bed treatment" of the acute psychoses are daily more and more recognized. To put such cases, dressed and on their feet, in the excited wards of an asylum is a tolerably wide departure from these principles of treatment. The results of home treatment, where isolation, rest in bed, absolute quiet and a sufficient nursing force can be obtained, show the superiority of such measures.

PSYCHOLOGY AND HEREDITY.[1]

BY ROBERT MACDOUGALL, PH.D., CAMBRIDGE, MASS.,
Instructor in Psychology, Harvard University.

It is commonly said that the great movement which resulted in the creation of our whole system of historical sciences had its origin last century in the work of certain German scholars who began to study the words of their mother tongue in a different way from that of earlier grammarians. These men applied to their problem a concept of great note in contemporary scientific discussion, namely, that of descent with cumulative modifications, and asserted that the verbal forms in use among a people at any given period could be intelligently understood only as parts of an historical process. There are many shades of meaning in the use of a single term, many analogies of use in terms having only the barest structural resemblance, many common elements in forms of widely varying application, which, taken as they stand, present a perplexing confusion of structure and of use. But to take them thus, said these scholars, is to cut out a fragment of tissue from its common body of life, to isolate an organ from the organism which gives it meaning, a process fatal to the purpose of one who seeks to understand assimilation or teleology. The living signification of the word can be understood only in its connection with the whole vital process of change in the language. Every variety of form and every shade of meaning is the result of a process of growth and a starting point for new development. No term is ever an isolated phenomenon springing up out of the void and arbitrarily affixed to a certain concept; each is a member of a genetic group, and by means of the material preserved in written records, they tell us, the scholar may go back to primitive root forms where these now widely separated variants unite in a single stem with some fundamental signification; and setting out from this point he may trace the family history downward to its latest descendants, observing the points of divergence where new forms and new uses of the form arise, and the process of cumulative differentiations by which new types are established, until the whole complex furniture of a modern civilized tongue is understood and accounted for under one or two simple concepts.

This new point of view, which created modern philology, was immensely fruitful, and in a series of brilliant and successful attempts was applied to a

[1] Read at the meeting of the Boston Society for Medical Improvement, December 4, 1899.

great variety of materials, with a result adequately expressed only in the total body of present historical knowledge; it created modern science. This is true in all but one particular, namely, that the point of view was not a new one. The historical method is basal in the work of one whole group of men whose functions are invested with a dignity and regarded with a gratitude not accorded to any other body of students; I refer to your own profession, gentlemen. The physician has been an evolutionist from the beginning. His work is a consistent endeavor to account for the present process of change in a diseased body as the outcome of definable preceding conditions, as intelligible only in the light of its own history. The explanation of the disease is resolved into a description of its origin and development. The physician regards the pathological condition as part of an orderly natural process, as over against those theologians who conceive it under the absolutely non-historical concept of a spiritual discipline or punishment for sin. You, then, after a fashion, have led the way in the application of the concept of historical development to the explanation of natural phenomena, and you are continuously and vitally interested, as a matter of practical import if not from a theoretical point of view, in the problems of fixity and variation of type, of heredity and acquisition, which are still so eagerly debated by opposing schools, and which we are met to consider here to-night.

The problem is one of origins. Every existing organism presents certain relatively permanent structural forms and characteristic ways of acting, and the work of the historical student is "to probe the dark backward and abysm of time," and trace out the conditions under which they were acquired and the factors which contributed to their development. In the course of this investigation, when a certain complexity of structure has been reached, relative interruptions are found to occur in the continuity of these conditions, breaking up the vital series into successive groups. In the simplest forms of life these nodal points are much more obscure; the unitary cell propagates by simple division of its protoplasmic matter, the independent life of each part having direct physical continuity with that of the original undivided cell; the ameboid organism on reaching a certain limit of increase in mass divides and becomes two individuals, each of which has indeed lost weight as compared with the initial cell group, but is materially as well as functionally identical with it; the same holds true of all those primitive forms of life which reproduce their species by any form of budding.[3] Both in the proliferation process of the cell and in the propagation of these multicellular protozoa, there exists a direct physical immortality which renders it misleading to speak of heredity as a source of individual variations. The physical continuity of the individual, as distinguished from that of its somatic units, is maintained from generation (admit the term) to generation, and the changes which take place must be viewed as occurring within the life of the organism, whether they result from the reactions which it makes upon its environment or derive from those unknown sources which, for lack of a descriptive term, have been called the *region of spontaneous variations*. In these primitive types of life the Lamarckian law is dominant, for each individual inherits by direct appropriation the characteristics acquired during presegmentational periods.

But when we pass from such simple creatures to those more highly organized forms in which reproduction is sexual, the process, though still of the proliferation type, and maintaining a certain physical immortality, becomes exceedingly elaborate and complex. The successive stages of the individual are exceedingly unlike each other, presenting in the highest types such contrasts as that of the mature human organism with the simple protoplasmic cell from which it has been developed. In these types, moreover, very much of the final structural form, and indirectly therefore of the functional activities as well, is due to some kind of prepotency in the contribution of the original germ cell, — call it the formula of its assimilative activity, or what you will, — and not to the surrounding conditions under which the individual develops. It therefore becomes a matter of pressing theoretical importance, as well as of practical value, to keep these two factors of determination distinct from each other, and to delimit their provinces in the development of the concrete life of the individual.[3]

Some of these characteristics are manifestly acquired by the organism within its own individual life, such as the ability to speak or write a particular language, the roughened hands and knotted muscles of the field laborer, the chronic indigestion resulting from a diet of fatty and starchy substances, or the groups of associated ideas which form one's knowledge regarding any special topic; others are as clearly traceable to the pre-existing assimilative type of the germ cell itself, of which nature are the general body plan and the conformation of its constituent organs, coloration of the skin, facial angles, pigmentation of the eyes and hair, and the like; while a third ill-defined group of elements presents such obscurity of origin that its sources form the debatable ground of science. The problem, then, is to trace out, both on the side of the physical organism and on that of the subject of consciousness, the elements due to inheritance of ancestral traits on the one hand, and to the direct influence of the environment acting within the limits of the individual life on the other.[4]

But it is not enough simply to account for the structure of the existing organism by referring each of its elements to one or two sources, its heredity or its environment; account must be taken also of the fact that cumulative variations exist. By heredity is meant the reappearance in the offspring of the characteristics, physical or mental, of the parent. If, then, the environment change, the plastic individual will vary in so far as the new conditions require a different adaptation from that demanded of the parent, but every generation will present the same material upon which the pressure of life conditions is to be exerted. This is not found to be the case; the curve of adaptation mounts more rapidly than the immediate influence of the environment working upon an unmodified material will account for. Heredity is not fixed; the type changes as well as the individual. There is, therefore, a third factor to be considered, namely, the appearance and inheritance of adaptive variations.

The question, then, is of the origin of variations, concerning which two possible sources have been pointed out: firstly, it is said the progressive change

[4] American Text-Book of Physiology: W. H. Howell (Editor), p. 931, ff.

arises from the process of adaptation itself — the theory of the inheritance of acquired characteristics; and secondly, that it springs out of the dark — the theory of spontaneous variations. The first view is based upon the very manifest fact of adaptation within the individual life. As in the psychological world every experience leaves its mark behind it and the residual traces of all previous experiences enter into and determine the character of the present event, so the results of the life experience of past individuals enter into and determine the nature of their offspring. The effect of this past experience was represented in an adaptation to the environment. Therefore to the acquired aptitudes of the individual are to be added the inherited results of the adaptation of preceding individuals. The process is a cumulative one expressed in a racial adjustment in the form of an accelerated curve. This is the popular view. There is an almost fatal facility about its application. It *ought* to be so; practical postulates assert it; the whole common range of our moral education assumes its validity. The evidence, at first sight, is enormously in its favor; practically no variation can be pointed to which it can not be made to cover.

The contrasted view [5] holds that acquirement is essentially a transient phenomenon, *intra-vital*, not *inter-vital*, affecting the individual only, not the race. The stock remains throughout uninfluenced by the acquired adaptations of the individual. Another source of variations must be sought. But there is none; heredity is the element of fixity, and all other real factors in the constitution of the individual are included under the term "environment." Variations, however, do appear. Whence? Out of the dark; they cannot be connected with any known sources, though favorable or unfavorable conditions for their appearance may be discovered. They are of the nature of sports or freaks and are hence called *spontaneous*. The phenomenon is an inter-vital one, the divergence from the ancestral type on the part of the offspring being independent of the acquired characteristics of the parents. The environment then acts simply as a selective agency, eliminating some and preserving others according as the sum of their variations renders them more or less fit to meet the conditions of life imposed upon the species.

Such a theory has to meet the very great difficulty that these spontaneous variations simulate completely the results of an inheritance of acquired characteristics. The trend of evolution being determined by the selective environment, the kind of spontaneous variations preserved by it are just such as would accumulate through the inheritance of training effects. The rudimentary wings of certain birds and insects native in the Oceanic islands is a case in point.[6] Circumscribed in the range of their feeding grounds, unpersecuted by enemies and relieved from long migratory flights, the whole set of conditions under which the individual lives tends toward a disuse of these organs, and the decreased length and shrunken muscles of the wings are just such as would be brought about by the inheritance of those atrophic conditions which are found to result within the life of the individual from non-use of an organ. But these same environing conditions acting purely as a selective agency upon variations spontaneously arising would tend toward the production of the same type through — to indicate one influence only — the destruction of such individuals as were led by their more developed wings into attempted migrations, or flights which brought them into the track of storms upon the open sea. The same ambiguity of evidence exists in regard to the thickened legs of domestic fowls, the shortened feet of pigeons, the blindness of cave animals, and a multitude of other facts [7] including the traditional instance of use-inheritance in certain professional aptitudes and sensory divergencies characteristic of those engaged in hereditary crafts and occupations.[8] A decisive argument in favor of the theory of sports would be afforded by instances in which the emergent variation was useless, clearly dissociated from the whole stream of life-serving activities in the individual and the race. The esthetic sense has been cited to this end, but its evidence is manifestly irrelevant, if for no other reason than its importance for sexual selection. The strongest argument in rebuttal of use-inheritance is perhaps the case of special adaptations in neuter insects, where there is no possibility of the transmission of characteristics acquired within the life of the individual, since the variety is a non-sexual, infertile one, from which the very fact of propagation is absent. Yet even for these staggering objections the Lamarckian finds a reply, and for the anomalous facts a place within his formula in the theory that the neuter insect is not a form in process of change, but a static type, originally produced through use-inheritance during a preneuter period, when transmission was an actual fact, and that further specialization ceased with the advent of infertility. Neuterness is interpreted as the last variation to appear, not a condition under which the adaptive changes themselves arose. The same difficulties thus lie in the way of those who deny and those who affirm use-inheritance, so that Weissmann admits that the whole force of his argument rests on the logical consistency of the hypothesis and not on any direct indubitable evidence.[9]

The appeal to residual structures and rudimentary functions, then, results only in a determination of the hereditary origin of these organs and activities in contrast with an acquisition within the life of the individual through his own purposeful reactions. Their presence has been of the utmost significance in establishing the fact of organic evolution and in tracing out the genetic connection of existing species,[10] but no light is thereby thrown upon the nature of their origin. Yet though ineffective for the solution of these contemporary problems of biologic evolution, such phenomena are of decided interest and importance for a study of the processes involved in the evolution of consciousness, for here our knowledge is at a stage where the inquiry still centres upon the relative importance of the two factors as *veræ causæ* and is concerned with the delimitation of the provinces of heredity and of acquisition.

The problems which this field of investigation pre-

sents are analogous to those of organic evolution, and the same methods are applied in both lines of inquiry. We seek to describe and account for the present concrete fact of individual conscious life. Leaving out of consideration the non-historical and unscientific category of miraculous gifts and divine revelation, the existing characteristics are referable to one of two sources: (1) the direct influence of the conditions under which the life is carried on; and (2) the inheritance by physical transmission of ancestral traits. I say inheritance *by physical transmission* because we shall find that mental inheritance of another kind exists as a *vera causa* of immense significance, and because the relation between the physical and mental aspects of development is a close but not complete parallelism. At a certain point in physical evolution, apparently as the concomitant of a particular complexity of structure, arises the phenomenon of consciousness. The determination of this point may be in dispute, but however decided, whether on the basis of the presence of that specific form known as a nervous system, or of the functions of assimilation and movement, from the point which marks that appearance onward through its whole range from the crudest sentience of ameboid life to the complex consciousness of humanity, the development has been a parallel one. In so far as mental life is conditioned directly on the presence of an inherited physical organism its character is predetermined. Our bodies are the same in all their main outlines as those of our forefathers; eyes, ears, skin and muscles are repeated, and our field of consciousness must therefore be one of visual, auditory and tactual perceptions and of motor reactions. Kind reproduces after its kind; our world is not that of the microscopic-eyed insect or the telescopic-eyed vulture; nor do we fly in the air, nor breathe the water, nor burrow, nor hibernate. The physical organism, that is, presents through successive generations a stable type of perceptive and reactive apparatus and therefore directly conditions the sensory material assimilated in the process of consciousness and the motor experiences in which its outgoing impulses are expressed.

Even this statement must be qualified. The *objects* of our world of consciousness are not given; what the inherited nervous structure makes possible is only the experience of pure sense qualities, red, hot, rough, sour and the like. The object must be constructed out of successive experiences through the co-operation of various sensory and motor elements. The fundamentally important fact in the world of our perceptive consciousness is this, that many elements of sense experience fuse together in the unity of one object perception. What is seen, felt or heard is not so much the sensation immediately present as the object of which it gives awareness. Perception, then, is not a primary function of the inherited structure; what is transmitted is a mere capacity for sensory stimulation whose mental coefficient presents a chaos of elements which are wrought up by the activity of consciousness into the syntheses of perception.[11]

There is, however, a region of obscurity, as in the case of organic evolution, in which complex emotional processes and teleological attitudes are presented whose origin is still a debatable ground. Such are the so-called expressions of certain primitive moods of feeling, the frown of anger, the sneer of dislike and contempt, the kiss of affection, which are interpreted on the one hand as a true expressive mechanism whose *raison d'être* is to make "manifest in the flesh" and communicable these qualitatively varying mental states; while on the other they are regarded as the residues of once useful reactions now fallen into desuetude; the frown prevents congestion of the optic blood-vessels during the anger fit, the sneer is an incipient unfleshing of the teeth for coming battle, the kiss is a rarefied essence of a smacking of the lips which accompanied a far different treatment of its object from that which the kiss now implies.

Among such complexes of emotional and active attitudes we should expect the clearest evidence of inherited structure in those which are not correlated with any practical end, for wherever the feeling or action is such as the conditions of life themselves would naturally call into being, the old insurmountable ambiguity returns that the action of a selective environment upon variations spontaneously arising tends to the preservation of exactly the same kinds of activity as would be fostered in the process of individual adaptation to such an environment. For example, the complicated motor processes involved in walking have been interpreted as due not to a process of learning on the part of the child, but to a series of changes within the brain substance, independent of the environment, and of the nature of a ripening process. It would follow upon this that in the case of two infants manifesting simultaneously the first signs of reactional irritability to stimulation from contact between the soles of the feet and the earth, if one were artificially prevented from carrying out the motor impulse in actual attempts at walking, and so restrained during the whole period occupied by the other child in learning the function, it would be found at the end of that time as fully able as it to co-ordinate the motor impulses in the complex movements of walking.[12] The bodily organism has been carefully explored for such residual structures, and over two hundred rudimentary organs have been pointed out.

The muscles which control the movements of the ear, scalp and other portions of the skin of the body have so degenerated that in most human beings they are incapable of reacting, and in all they have ceased to be employed for the dislodgment of insect pests; while in the horse analogous muscles are used to sweep the flank or side clear of flies by one comprehensive vibration. The vermiform appendix, which in some animals forms an important member of the digestive system, is in man but a shrunken sac, notable only for the dangers which it holds for human life. The corner fold of the eye is a fragment of an apparatus identical with the nictitating membranes of birds, but now destitute of functioning power. The same holds true of the appearance of transient functions and also of the origin of many which are permanent. The probable dependence of the function of walking upon a ripening process in the brain centres is determined by the constitution of its inherited structure. To this may be added in further illustration the orderly representation in the development of voluntary movements within the individual human organism of successive phases of phylogenetic evolution. The earliest function of the fore-limbs in the development

[12] James: Principles of Psychology, vol. ii, p. 406. Locomotion in calves, which begins within a few hours of birth, and in chicks follows at once upon their emergence from the shell, cannot be regarded as the result of a process of learning.

of life upon the earth was that of swimming; when a terrestial mode of existence supplanted the earlier aquatic life, a new application of these members was made in grasping, pulling and holding on, and latest of all arose those complex forms of manipulation, involving independent use of the various fingers and the opposition of the thumb. The same succession of function forms is now manifested in the infantile development of motor activities; swimming movements appear first, those of grasping and pulling follow, and not until much later are the fingers used for touching objects or does the hand begin to make those beautiful and elaborate adjustments characteristic of mature life.[18]

The phenomena of the mental world, on the other hand, have barely been scrutinized from this point of view. Yet these rudimentary organs and functions of the soul surely exist, the echoes of the long past, survivals of uncouth activities and strange ancestors,

"Whose distant footsteps echo
Down the corridors of Time."

We need a paleontology of the soul, tracing its progressive adjustment to the changing environment, the sloughing of old, the acquisition of new functions and sentiments, with its consequent explanation of atavistic tendencies and facts of reversion, instinctive impulses unintelligible to ourselves, automatisms which now appear as monstrous and inexplicable twists of our nature, and all the cumbering rubbish of ancient forms and activities which no longer fulfil any useful function, but which because they have so long been ours we cannot shake off.

The truancies of the child, insistent in the face of punishment, the unrest and aversion to settled modes of life which seize upon all of us at certain seasons, the curious impulses to vagrancy which appear at all ages and in all classes, driving their subjects forth into the wilderness, together with the whole tramp problem, point to the outcropping of some old migratory instinct in the human race whose purpose and even existence had been forgotten. Collecting manias of coins, stamps, hats, sticks, newspapers, and the like, and the various forms of pathological secretiveness met with among the insane, are interpretable as survivals from a period where the hoarding instinct was as important a function in the life of the human race as it now is in that of the squirrel and dog.

(To be continued.)

ON THE ADVISABILITY OF A MORE OR LESS GENERAL EXPLORATION OF THE ABDOMEN WHEN IT HAS BEEN OPENED FOR AN OPERATION.

BY JOHN HOMANS, M.D., BOSTON.,
Visiting Surgeon, Massachusetts General Hospital.

It has happened to me to discover very happily in several instances conditions and diseases entirely different from the one for which I had opened the abdomen, and it seems to me as wise as it is harmless to make a rapid examination of the abdominal organs other than those we are operating upon, when a favorable opportunity occurs. In this way I have three times removed gall-stones, whose presence was unsuspected, and whose removal did more for the patient's recovery and perfect subsequent health than did the removal of the tumor for which the abdomen was opened. I do not mean to recommend the lengthening of short incisions in order to explore. If the incision has been made an inch and a half long for an appendectomy, or for the removal of an ovarian tumor, or for an easy cholecystotomy, I would not lengthen it, but if we have removed a good-sized pelvic tumor, or a kidney, or for any purpose have made an opening sufficiently large to get the hand into the abdominal cavity, I think it is a good plan, particularly where there are any unexplained symptoms of pain and discomfort, to put in the hand and explore, particularly in the region of the gall-bladder, stones in which give rise to a great variety of symptoms and make life a burden.

So in regard to the appendix, which is often found diseased in connection with salpingitis and sometimes adherent to the tube. It is not always easy to say which of the organs was originally diseased, nor to decide whether the appendicitis follows the affection of the Fallopian tube or whether the Fallopian tube was infected by the appendix.

As illustrations of the wisdom of the course I have been advocating I will relate briefly the following cases:

Mrs. B., thirty-eight, emaciated and anxious looking, was sent to me by Dr. Spofford of Cavendish, Vt., in March, 1895. Her symptoms were nausea for last eight years at various times, she not being able to eat and retain solid food for eight months. She had become very thin and was suffering much from pain and backache, and felt as if a string were tightly tied around her waist; she stooped in walking and moved with much pain and difficulty. She has been treated in various hospitals during the past seventeen years and her pains and aches have been considered reflex from her diseased pelvic organs. She has had two children; the youngest was seventeen years old. Her uterus was retroverted and fixed, the tubes and ovaries were enlarged, prolapsed and adherent. Her catamenia had appeared once in the last fifteen months. Her body was covered more or less by spots caused by scratching, but no pediculi were found.

Her stomach was washed out daily by Dr. Pease and she improved somewhat; her vomiting became less frequent, but her backache and pelvic pain and tenderness continued. On April 6, 1895, with great difficulty, a left adherent tubo-ovarian cyst was dug out. The hemorrhage was so persistent that I thought of tying the internal iliac artery, but I finally clamped all the bleeding points with five long clamps, which I left in the abdomen with their handles outside the abdominal walls. I then inserted my hand through the wound and felt of the gall-bladder, which I found full of stones. The wound between the umbilicus and pubes was then sewed up around the clamp handles and another incision was made parallel with the cartilages of the ribs, over the gall-bladder. Ninety-seven gall-stones were then removed. She vomited incessantly for a week, then improved and went home at the end of five weeks perfectly well and able to eat anything. She grew fat and strong and continued comfortable for more than a year.

In December, 1896, her old symptoms of vomiting and pain had returned, and I opened the gall-bladder again and removed seven calculi, which had formed around pieces of silk which had united the gall-bladder

[18] A. A. Mumford: Survival Movements in Human Infancy, Brain, vol. 20, pp. 289-306 (1897).

to the peritoneum, just as alum crystallizes around a thread suspended in a hot saturated solution.

This case of recurrent gall-stones was published in the *Annals of Surgery*, with a colored plate showing the stones and ligatures, and was subsequently distributed as a reprint.

Mrs. M., forty-two years old, was brought to me in May, 1897, by Dr. Dibble, of St. Stephen, N. B. She had a lobulated abdominal tumor which was a sacculated right kidney filled with pus and calculi. This was removed by abdominal section and after its removal I inserted my hand and felt of the gall-bladder; it was full of stones. Without enlarging the incision the gall-bladder was opened and nine stones, varying in size from a No. 6 shot to a robin's egg, were removed. Another stone was impacted in the common duct but, after much manipulation, was finally worked up into the bladder. The remaining kidney worked beautifully, the wound healed by first intention except when the gall-bladder was draining, and the patient left the hospital perfectly well on the twenty-first day after the combined nephrectomy and cholecystotomy. Had I not made this manual exploration the patient would have gone home but half cured.

Mrs. D. was sent to me in March, 1899, by Dr. Witherlee of Castine, Maine. I found a fibroid tumor the size of a large orange, and to the irritation of this tumor was ascribed her digestive symptoms, which were quite severe. For three years she has been good for nothing and could hardly eat anything. Formerly she weighed 180 pounds and now weighs 124. On March 20, 1899, I removed the fibroid tumor, and then inserted my hand, passed it up to the hepatic region and found that the gall-bladder contained one large stone. The abdominal incision was lengthened upwards to a point two inches above the umbilicus, and the fundus of the gall-bladder was drawn through the wound and a stone one inch square was removed. The bladder was immediately sewn up and the wound closed without drainage. Her dyspeptic symptoms were much relieved by suggestions from Dr. E. G. Cutler, and she is now well and strong and can do and eat what she likes, and has nearly regained her former weight. Other cases could be cited, but it seems to me that those above narrated justify and, indeed, should compel exploration whenever feasible.

Clinical Department.

A CLINICAL STUDY OF HEROIN.

BY JAMES R. L. DALY, M.D.,
Resident Physician, Seton Hospital, Spuyten Duyvil, N. Y.

A NEW agent in the treatment of cough, at present in wide use and attracting considerable attention in the medical world, is heroin. It is a derivative of morphine — the diacetic acid ester — and is a white crystalline powder, almost insoluble in water, but readily soluble in water to which a few drops of acetic or hydrochloric acid have been added. It possesses many advantages over morphine as a respiratory sedative, among which the following may be mentioned: (1) It prolongs respiration, and at the same time increases the volume of each inspiration, making it a remedy much to be desired in the treatment of cough; (2) it is not a hypnotic; (3) absence of danger of acquiring the habit; (4) it does not weaken the respiratory apparatus; (5) it does not cause unpleasant disturbance of the stomach or intestines; (6) it can be prescribed in cases in which heart complications occur without risk of any deleterious effect upon that organ; (7) the ratio of the therapeutic dose to the toxic dose is considerably smaller than that of morphine.

The following cases, taken at random from a clinical field of over 100 cases of pulmonary tuberculosis in all stages of the disease in this hospital, will best serve to illustrate the efficacy of the drug:

CASE I. A. B., male, age thirty-two, clerk, entered hospital with history of pain in left side, which began about four months before admission; night sweats; hacking cough, most troublesome at night, with markedly diminished secretion, and slight dyspnea at varying intervals during day and night. Physical examination revealed consolidation of upper lobe on left side, and of apex on right side. Mist. codeia, one drachm, three times daily and at midnight was administered, and continued for two weeks, but with little result. At the end of this period the codeine was stopped and heroin substituted in doses of one-twelfth grain three times daily and at midnight. In four days the cough began to lose its hacking character, and the secretion became more abundant; in about one week the cough could only be observed in the morning and evening, and remained sufficiently loose to render the patient very comfortable. No dyspnea was observed a week after the heroin was begun and breathing still remained free. Mean respiration during first twenty days in hospital, A. M., 29; P. M., $29\frac{3}{5}$. Mean respiration for twenty days following the first administration of heroin, A. M., $24\frac{4}{5}$; P. M., $25\frac{1}{5}$. For the night sweats the patient was given a pill of zinc oxide, two grains, with extract belladonna, three-tenths grain, for three nights without result. On the third night heroin was substituted for codeine, and on the second night following the sweats ceased.

CASE II. On admission the patient complained of severe and painful cough throughout the day and night; expectoration scanty, and obtained only after considerable effort. Physical examination showed both lungs involved with cavity in right middle lobe. The patient was given heroin, one-twelfth grain, three times daily at first, and shortly after the dose was increased to one-sixth grain. After one week of heroin the cough was diminished to a marked extent, and the pain heretofore associated with the cough had disappeared.

CASE III. Patient entered hospital complaining of "smothering sensation" in chest, with slight pain. Heroin, one-twelfth grain, three times daily and at midnight was administered, and in three days this "smothering" had disappeared, but not permanently, as the patient has since complained of it; but he says that it is not as severe or as lasting as before he was put on heroin. Of course, the cough which was present was greatly loosened, and this it was that gave the patient relief.

CASE IV. Patient entered hospital complaining of hard, dry and persistent cough, most troublesome towards evening. Expectoration scanty, and effort of coughing caused great pain in chest. The patient was given heroin, one-twelfth grain, and in three days the cough became soft, and expectoration became quite free. The pain in the chest had, of course, dis-

appeared with the hard cough. The patient remained very comfortable for a month, when heroin was discontinued, because I believed it to be the cause of a certain heavy feeling of which he complained. The cough, however, again became severe and hard, and heroin was repeated in the same dose as before. In three days the patient was freed from the distressing cough, and that "heaviness" has not returned. Mean respiration during period in which the patient was taking heroin, A. M., 24; P. M., 26. Respiration became more rapid while the patient was without the drug, averaging, A. M., $25\frac{3}{4}$; P. M., $27\frac{1}{4}\frac{1}{4}$.

Case V. Patient has been in hospital for some time. Complained of severe cough beginning about midnight and lasting until morning. Heroin, one-sixth grain, was administered every night at 10.30. The cough was absent on second night that heroin was administered, and has not since distressed the patient.

Case VI. Patient complained of severe night sweats, and was given atropine, $\frac{1}{100}$ grain, for two nights without success; on the third night heroin, one-sixth grain, was given one-half hour after atropine, and sweats ceased.

Case VII. J. F., male, age thirty-two, laborer. If any case can be said to be a striking example of the efficacy of a remedy this case is certainly that one. The patient entered the hospital with very slight but hard cough and a history of marked and constant night sweats. The latter had inconvenienced the patient for seven weeks previous to entrance, without an intermission of a single night. Mist. codeia, one drachm, three times daily, was administered for the cough, and an attempt was at once made to check the night sweats. Camphoric acid had been a favorite with me in the treatment of this symptom, and I accordingly gave 20 grains at bedtime, and repeated the same dose for four succeeding nights, but without result. Then atropine sulph. and ac. sulphuric aromat. were tried in the proportion of one-fiftieth of the former and 10 minims of the latter, but again without a favorable result. This was given for five nights. Atropine sulph. alone was tried in dose of one-fiftieth grain for a week; still no response. Next was tried a pill of zinc oxide, two grains, and extract belladonna, three-tenths grain, for five nights, and this, like the rest, failed. Pilocarpine was next tried in dose of $\frac{1}{100}$ grain, but it only increased the sweating. Next in order came warm baths, and then bathing with ac. sulphuric dilute, but these met the same fate as all the preceding. Then I decided to give the sweat glands a rest, and for a week nothing was administered for the sweating, and at the end of this time atropine sulph. was repeated in dose of one-fiftieth grain, but without result, until about the fifth night of the administration of the latter the codeia mixture was discontinued and heroin substituted in dose of one-twelfth grain three times daily. On the third night of the administration of the latter the sweats decreased to a great extent, and on the fourth night ceased altogether. The heroin had replaced the codeia mist., not because of the sweating but because of the hard cough, which did not improve; and since the patient had been taking the former the cough has loosened considerably, and he now experiences marked relief. I regard this case as typical, not of the curative effect of heroin on the night sweats, but rather of the quality of the drug to assist the ordinary anhydrotics when, given alone, they fail.

Case VIII. Case of tubercular laryngitis. Patient complained of severe sore throat, which prevented deglutition. Pills of heroin, one-twelfth grain, were administered every three hours, and kept the throat in a condition of anesthesia for about one to two hours, rendering the patient fairly comfortable, and most of the time free from pain. It is unnecessary for me to mention that the patient was instructed to dissolve the pill slowly on his tongue. Two other marked cases of tubercular laryngitis were temporarily relieved by the administration of heroin in this manner.

These cases are fair samples of the results obtained by the administration of heroin. In almost every case in which it has been tried it has been of some service in the alleviation of cough, be that service ever so slight. Even the advanced cases have been to a certain extent relieved. I found, however, that the more favorable results were obtained in those cases in which the disease process had not advanced to too great an extent. In this class of cases the drug never failed to loosen a hard cough and produce free expectoration, giving marked relief from pain when present. I regard it as unequalled as a sedative in the treatment of cough of pulmonary tuberculosis, and venture to say, although I have not tested it in cases of cough in other pulmonary affections, that it will act equally well in such cases.

The smaller dose of one-twelfth grain is sufficient to afford relief in most cases, certainly in the milder or earlier ones, but in some instances it was found necessary to increase the dose to one-sixth grain, as after a time the smaller dose seemed to lose its effect upon the patient. Sometimes when heroin had been taken for a long time, it was found to be a good practice to stop it and give codeine, or some other sedative, for one week, and then renew the heroin at the end of this time. In this way the drug acted as well when renewed as in the beginning of the treatment. It is true, however, that heroin produces its effect for a much longer period than does any of the other sedatives used in this affection.

I said it was not a hypnotic, but the fact that it relieves the distressing cough which is often the cause of many sleepless nights, and thus ensures a natural sleep, obviating the necessity of using hypnotics, should not be overlooked.

I have very carefully watched the temperature charts for any evidence of its action as an antipyretic, but have been unable to find that it produces any effect whatever on the temperature. It certainly possesses no quality as a preventive or cure of the chills so persistently present in the later stages of tuberculosis. Like the respiration, the pulse is rendered fuller and slower. In 10 cases observed the mean pulse rate was reduced about four beats per minute; in one case the rate was reduced eight beats per minute. By its action upon respiration and its ability to relieve cough and promote excretion of secretory products, it manifests a decided effect upon the dyspnea.

I regard the influence of heroin on the night sweats as second only in importance to its influence as a sedative for the cough. In the cases cited its quality as an adjuvant to the ordinary remedies in checking the sweats is well marked. In six other cases favorable results were obtained in either checking or markedly decreasing the sweat by the administration of heroin in conjunction with one or another of the ordinary

anhydrotics. Its action in this particular is best appreciated after meeting failure in using the ordinary agent alone.

The cases of tubercular laryngitis mentioned are typical of its action as an analgesic in the treatment of the painful throats of this affection. In these cases it afforded considerable relief from pain for periods of about one to two hours following the administration of the pill.

In regard to its influence on respiration, I have carefully noted 19 cases, and have found that in each case the mean respiration A. M. and P. M. has been reduced from two to five, and in some cases as high as seven per minute.

No action on the intestines was observed, except, perhaps, a slight tendency to constipate if given in larger doses than one-twelfth grain. Of this, however, I will not be certain, as in the great majority of cases this action was not apparent. In some cases it has been noticed to cause a disturbance of the stomach. One patient complained that the drug caused considerable nausea shortly after taking, while with others the disturbance can best be described by using a term applied by a patient to the condition of his stomach after taking heroin — "squeamish." One complained of complete loss of appetite whenever he took the drug. In all, some disturbance was noted in five cases out of upwards of 70 patients taking the drug. I should add, however, that two of those who complained of disturbance of the stomach while taking heroin were later able to use it without noticing any ill effects. Another, and, in my opinion, the only real objection to heroin, is that in certain cases the larger dose of one-sixth grain was found to cause a feeling of heaviness during the day. To quote a patient, "I feel heavy and as though I want to sleep, but if I try to do so I find that I cannot." This was observed in four cases. The drug did not in any instance produce this effect when given in the smaller dose. But the chief use to which heroin can be put is as a sedative for the cough and to prevent the distressing and disagreeable stagnation of secretory products in the lungs, particularly in cases of pulmonary tuberculosis. No drug can compare with heroin in this particular. Cases that have come into the hospital with painful and almost constant cough, with inability to raise the sputum, resulting in fetid breath and more or less dyspnea, have been almost immediately relieved of pain, and the expectoration rendered freer, with decrease in the dyspnea, by the administration of heroin in doses of one-twelfth grain three times daily.

A CASE OF OLD SHOULDER DISLOCATION.

BY FRANK E. PECKHAM, M.D., PROVIDENCE, R. I.

THE subject of old dislocations of the shoulder joint has been thoroughly worked up by Dr. F. B. Lund, who found 24 cases up to 1897, treated at the Boston City Hospital. The oldest case was one of one and one-half years' duration, treated by open incision and resection of capsule. The following case was so interesting to me that I venture to report it quite fully.

The patient, a girl of sixteen years, fell down stairs July 10, 1897, striking on the right shoulder. At that time there was pain and disability, but the dislocation was not recognized and the treatment consisted of application of liniments, etc. Early in the year 1899 she was examined by a number of surgeons, all of whom advised against operation. In May, 1899, the patient came under my observation and care. At this time there was no motion in the joint, and the patient was able to do but very little work of any kind with her right arm, any attempt at using it causing considerable pain. I probably should not have operated, but the girl was extremely anxious to have something done, and her uncle and aunt, with whom she lived, also urgently solicited surgical interference; consequently, after having it distinctly understood that all that was promised was an "attempt" to do something, operation was undertaken. The reasons, therefore, for this operation were disability, pain when the arm was used very much and the demands of the patient and family that something be done. The disability was very marked; about all the girl could do was to wash dishes and this not very well, the motion being entirely scapular. A radiograph was obtained which showed a large gap below the acromion process, but whether a fracture existed could not be made out.

May 10, 1899, one year and ten months after the accident, operation was undertaken. Ether was the anesthetic, and the usual aseptic precautions were taken. The posterior surface of the shoulder was selected for the incision in order to avoid all difficulty with the large vessels and nerves. A circular flap was turned up, with its convexity downward exposing the muscles beneath. The deltoid, supraspinatus and teres minor muscles being divided, the capsule of the joint came immediately into view. This was stretched tightly downward, and on being divided the humeral head came into view just below the glenoid fossa, with the neck projecting diagonally forward, in a line perpendicularly downward from the coracoid process. The head of the humerus was attached to the neck of the scapula below the glenoid fossa, by what seemed to be bony tissue. This union was destroyed by chisel and mallet, and then the difficulty began. Finally, by a very broad and blunt periosteotome used as a lever under the anatomical neck and the assistant pushing up on the arm with all the force possible, it went into place. The shoulder was held in this position while capsule, divided muscles and the incision were sutured, dressing applied and shoulder bandaged with firm support under elbow.

After a few days, the shoulder was manipulated daily in order to preserve mobility if possible. This was done under chloroform two or three times, but motion gradually disappeared and all treatment ceased a little less than one month after operation, the head of the bone remaining firmly in its socket.

The three reasons for operation as stated above were disability, pain and the family demand. Treating these reasons in the reverse order, the family demands were satisfied. The pain has disappeared. The disability is much less with only scapular motion when the head of the bone is in its socket, than scapular motion with the humerus in the awkward position as described above. The patient can now not only wash dishes, but sweep, scrub floors, and, in fact, do about all the housework. Lastly, the patient and her family all feel that a great improvement has been obtained and are grateful for the relief.

Medical Progress.

REPORT ON DERMATOLOGY.

BY JOHN T. BOWEN, M.D., BOSTON.

ENDOTHELIOMATA OF THE SKIN.

Spiegler,[1] of Vienna, reports several interesting instances of cutaneous tumors, which were remarkable both from their clinical appearances and histological findings. Certainly the clinical appearances, judging from the illustrations and description of the first case particularly, were, as Spiegler says, uncommon and striking. The first case was that of a man of sixty-six years of age, with good family history, who dated the beginning of his affection nearly forty years before, and who ascribed its beginning to an injury which he had received on the scalp, a tumor appearing at the site of the wound. Others were gradually added to this in the vicinity. When seen, the patient presented an extraordinary appearance, the front and sides of the scalp and both temples being covered with about forty tumors, from the size of a bean to that of an orange, somewhat resembling billiard balls. They were of firm consistency, covered partly with thin, smooth, adherent skin, which was in places superficially excoriated and ulcerated, and although forming a sort of hood by their connection with one another at the base, there was no real confluence. Besides these tumors, there were some small tumors the size of a pea, situated at the edge of the hair on the forehead, which were covered by an elastic pouch of skin and resembled fibroma molluscum. On the back there was a tumor the size of the fist, as well as a number of small nodules. All the tumors were removed surgically, and the defect supplied by skin grafting. Pieces from eight different tumors were examined histologically and identical appearances found in each. The tumor was found to be made up of collections of cells surrounded by a capsule and arranged in circles, ovals or ribbons, which in places extended nearly to the epidermis. The masses of cells often contained cavities which were filled with a structureless, homogeneons substance, staining pale red with eosin. The connective tissue between the cell masses and ribbons showed in places large lymph vessels. The cells which formed the peripheral part of the nests and ribbons had their long axis in the direction of the radius of the plane, and were of an epithelial appearance, whereas the nuclei of the cells in the interior of the masses presented a smaller round or polygonal form, and were less easily stained and quite irregular in their arrangement. All of the masses were surrounded by a narrow seam of homogeneous substance. In certain places capillaries were found with thickened wall, from which projected outward large cylindrical cells, arranged perpendicularly to the cell wall.

The second case was that of a daughter of the one just described, forty-four years of age, who presented six tumors of the scalp from the size of a pea to that of a bean, and one upon the temporal region, one of which had existed for ten years. Histologically they were exactly like those of the first case.

In the third case, that of a woman of forty-four, very numerous, closely aggregated tumors from the size of a pea to that of a hazel nut, corresponding in appearance with those of the first case, covered the scalp, with bundles of short hair between the individual lesions. There were also a few tumors on the body. The same histological appearances were found in this case as in the two preceding.

On searching the literature, the writer has found several instances of tumors, affecting chiefly the scalp, where the clinical appearances closely resembled those of the three cases reported, and three of these are pictured in connection with his own cases. In one case, which is reproduced from Hutchinson's "Archives of Surgery," different individuals of the same family had been affected with tumors of the scalp, throughout three generations. In one case there was apparently a malignant change in the tumors.

Spiegler rejects the name perithelioma, proposed by Hildebrand and Kollaczek, and considers it was shown in his first case that the tumors were produced by a growth of the cells of the capillaries, the endothelial cells. They grow without further connection with the vessel wall, until they form the network of cell masses and ribbons. Therefore the name endothelioma is justified.

It is further remarked that it is curious in how many clinically different lesions these same histological appearances have been observed. Jarisch has maintained that the multiple benign epithelioma owes its origin to the growth of the endothelium of the vessels, and lesions similar to xanthoma planum, as well as a warty-looking tumor, have been found by Spiegler to possess this same histology. In conclusion, the fact that his first two cases were in father and daughter and that in Ancell's case tumors that were of presumably the same nature were observed in three generations in different members of the same family is adduced in support of an hereditary origin.

MALIGNANT TUMORS GROWING FROM SOFT NEVI.

Waelsch,[2] assistant at Pick's clinic in Prague, discusses the question of the relationship of tumors that grow from soft nevi, or "moles," to carcinoma. He relates the case of a woman of fifty-six years, who presented a tumor over the right shoulder blade that had made its appearance upon a nevus six months previously. She had lost much flesh and suffered from dizziness, headache and loss of appetite. The tumor was of moderately firm consistency, dark-blue color and fungous character, and in parts was ulcerated. About this tumor were a number of small nodules from the size of a pin's head to that of a pea. The glands upon the right side of the neck were enlarged, as were also the supraclavicular glands. In the left axilla was a large mass of enlarged glands. There were no symptoms that could be referred to the internal organs. During the patient's stay in the hospital the tumor increased in size and became more ulcerated, and the general cachexia increased. Histological examination showed that the tumor had its seat in the corium and consisted of round and elongated masses of cells which had every appearance of being derived from epithelial cells.

The second case was that of a man of forty, who had had on the skin of the abdomen a smooth dark brown spot for a great many years. A black verrucous growth had made its appearance here six months

[1] Spiegler: Archiv f. Derm. u. Syph., 18 9.

[2] Archiv f. derm. u. Syph., 1899.

ago, which had progressed to its present size. It was sharply bounded from the sound skin, and had a papillary appearance, with fissures. In the left inguinal region the glands were enlarged and fused together to form a tumor. The growth upon the abdomen, as well as the glandular tumor, was excised. The microscope showed in the former, nests of epithelial cells and enormous quantities of pigment, and in places a direct connection could be traced between the cells of the tumor and those of the overlying epidermis. No pathological changes were found in the lymphatic glands.

The third case concerned a man of thirty, and the tumor had gradually grown from a nevus of the skin of the breast within three months. It was a fungous-looking growth attached to the skin by a pedicle, ulcerated on the surface, surrounded by small satellite tumors resembling mulberries or raspberries. There was not much pigmentation except on incision, when one-half of the base was seen to be deep black. Microscopically about the same appearances were noted as in the preceding cases.

The conclusion is therefore reached that in these cases we have to do with epithelial neoplasms, which have developed from pre-existing cell deposits of an epithelial nature, and which, in the appearance and arrangement of their cell elements, observe a perfect identity with the pathological soil from which they have sprung. In this connection no attempt is made to deny the possibility of the existence of true alveolar sarcomata but to emphasize, with Unna and Hodara, that those malignant tumors of alveolar arrangement which develop from soft nevi are to be expelled from the sarcomata and classed with the epithelial neoplasms. It is further contended that these tumors developing from embryonic cells afford a further argument in favor of Cohnheim's view of the etiology of tumors in general.

A MANIFESTATION OF LEPROSY ON THE SCALP.

Morrow [3] speaks at the outset of the tendency of many dermatoses to select or to avoid certain localizations, and remarks that locality in this way furnishes often a valuable aid to diagnosis. Thus in the eruptive fevers, psoriasis and some forms of eczema much information may be offered from the seat of the affection. This is true also of leprosy in a marked degree. The tubercular forms of leprosy almost always make their first appearance on the face, hands or feet or about the ankles. The erythematous forms of tubercular leprosy are almost always transient in duration and often appear and disappear a number of times before the tubercular infiltration is produced. On the contrary, the erythematous appearances of the anesthetic form are usually permanent. The anterior surfaces of the body are usually the ones affected in the tubercular form, while the anesthetic affect the posterior surfaces. In a tubercular leper it will usually be found that the tubercles are most in evidence on the face, the front of the ears, the dorsum or forearms and hands, the anterolateral aspect of the thighs, the front of the knees and legs, and the dorsal aspect of the feet. In the anesthetic form the earlier spots may appear on the face and front and sides of the ankle, but later we find a predilection for the buttocks, the back of the shoulders, and the posterolateral aspects of the body generally.

[3] Journal of Cutaneous and Genito-Urinary Diseases, January, 1900.

No region of the body can be said to be absolutely free from leprous lesions, yet in contrast to the face and limbs the trunk is comparatively immune. Hutchinson has no examples of portraits of leprous lesions on the trunk, yet such cases occur in countries where the disease is endemic. The glans penis is usually spared, as well as the palms and soles, the region of the neck, and the temples. Almost all authorities state that the hairy scalp is absolutely free from lesions. There may be lesions on the face, forehead and at the roots of the hair, but here they cease, so that the hair of the head remains intact, while eyebrows and beard may have totally disappeared. Hebra and Vidal alone speak of the occurrence of tubercles and infiltrations on the hairy scalp as a great rarity.

Morrow relates the following case, where leprous manifestations occurred in this unusual locality: The patient was a man of forty-seven, born in Bermuda. He had been a sailor and had visited many different parts of the world. He had first noticed a spot on the middle of the forehead sixteen years ago. This had gradually spread downward over the nose, cheek and upper lip, and had involved, also, the forehead and hairy scalp. He had had peculiar stinging sensations in the face for years, and of late some numbness. The eyelashes had disappeared, but the eyebrows remained. On the left side of the scalp the patch extended backward behind the ear to a point half-way between the ear and the occiput. The margin of the patch was the seat of hyperpigmentation. There were also two circular patches as large as the palm, one on the left deltoid region, and one on the lateral surface of the left leg, of eighteen months' duration, and a circular patch on the right foot. He had had twitching of the muscles of the toes and loss of feeling in the instep for over a year. The peroneal and ulnar nerves were enlarged. He had had sensations of numbness in his fingers and arms.

EXANTHEMATA IN GONORRHEA.

Buschke,[4] Lesser's assistant in Berlin, has grouped together the various forms of cutaneous lesions that have been shown to accompany gonorrhea. He remarks that the whole question of metastases in this disease has been placed on a more stable footing since the gonococcus has been demonstrated in the metastatic foci, and it has been shown that severe endocarditis and severe and frequent joint affections are due to this cause. Bennecke has asserted that gonorrhea loses its simply local action much more easily than has been supposed, and that the micro-organisms, gaining access to the blood, are frequently the cause of metastatic complications. The manifestations on the side of the joints and tendons are the most frequent, next those of the heart, while those of the skin come last. Three cases are related, the first that of a man who developed in the course of a pretty chronic gonorrhea pain in various joints, with effusion and an endocarditis. At the same time there appeared an eruption which was made up of superficial lesions of an urticarial character, and deeper infiltrations, similar to erythema nodosum. There was also an enlargement of the spleen and a rise of temperature. These symptoms appeared and disappeared several times, and it was thought probable that a new infection of the urethra was continually occurring from the dis-

[4] Archiv f. Derm. u. Syph., May, 1899.

eased prostate. Although it was considered that the skin affection was due to the gonorrhea, and belonged with the other symptoms, it was admitted that a complication with erythema nodosum could not be absolutely ruled out.

In the second case, that of a woman, there was an acute gonorrhea of the urethra, cervix and rectum, with the formation of a gonorrheal fistula. There appeared, in the acute stage, effusion into the joints of the feet and inflammatory nodules in the skin, similar to erythema nodosum. In the course of the affection a dry pericarditis developed without fever.

The third case concerned an epileptic, who had been taking bromide of potash continually. In the course of a gonorrhea he developed painful nodules on the lower limbs accompanied by pains in the joints. The case is weakened perhaps by the fact that a drug capable of producing eruptions had been taken, but it is pointed out that the bromide rarely if ever produces this clinical form.

In none of these cases were gonococci found in the blood or in the skin lesions.

The eruptions that have been shown to follow gonorrhea may be divided into four groups, simple erythema, eruptions like that of erythema nodosum, hemorrhagic and bullous dermatoses, and excessive cornification.

(1) *Simple erythema.* — The greater number of observations deal with this type, and it is probable that some of them are due to the balsams that have been given. Other cases are cited to show that an acute scarlatiniform erythema may occur in the course of a gonorrhea, at a time when no balsamic drug has been administered, and that such drug may be given afterward, without producing any cutaneous manifestation. Such cases have induced some writers to believe that the greater part at least of the erythematous eruptions that have been attributed to the balsams are in reality produced by the gonorrheal infection. As a transitional form from the erythematous to the nodular, a case is related where in the course of a gonorrhea an eruption partly scarlatiniform and partly urticarial occurred, when there had been no medicine taken internally. The only other possibility was that the effect might have been produced by the injections of sublimate solutions.

(2) *Urticaria and erythema nodosum.* — In this class belong the cases described by the writer in which the eruption took the form partly of superficial papular efflorescences, partly of cutaneous and subcutaneous nodules.

(3) *Hemorrhagic and bullous eruptions.*— In many of these cases there was also a complication with erythema. Vesicles and bullæ or purpuric patches appeared over the body, sometimes accompanied by a rise of temperature, and in almost all instances by arthritic pain or effusion. In one case an endocarditis occurred at the same time.

(4) *Hyperkeratosis.* — This interesting condition has been observed as a sequel of gonorrhea only in the last few years. In a case of Vidal's a gonorrhea contracted in February was followed in April by the appearance of thick, horny accumulations on the right knee and later on the hands and feet, especially the palms and soles. In May there were arthritic symptoms. The hard, horny patches were later on quite symmetrically distributed over the whole body and some of the nails were lost. The affection lasted about nine months. A fresh gonorrheal infection was followed by a similar eruption, running the same course. In a case of Jeanselme's the right hip and both knee-joints became swollen and painful a week after the appearance of a gonorrhea. Three weeks after the rheumatic symptoms, horny plaques made their appearance on the dorsal surfaces of the toes, and also on the outer and inner borders of the feet. There were no inflammatory appearances at the base of the lesions. The affection lasted about six weeks. Jeanselme's theory was that some central nervous lesion was caused by the gonorrhea which produced this symmetrical, trophic process. In a third case, of Chauffard's, there were two attacks of gonorrhea accompanied by severe general symptoms, endocarditis, multiple arthritis, epididymitis and nephritis, and each of these attacks was accompanied by keratoses on the feet, back, penis and thigh. Microscopically there were inflammatory appearances in the papillæ and hypertrophy and increased cornification in the epidermis.

Discussing the gonorrheal eruptions as a whole, Buschke calls attention to the multiformity of the manifestations, that is, erythema, papules, nodules like erythema nodosum, the formation of bullæ, purpura, and exaggerated cornification. The eruption is not confined to particular localities, but may be anywhere, although the scalp is a part usually spared. The mucous membrane of the mouth, throat and eye are not spared in the very acute forms. The eruption develops very quickly, but is very variable in its further course. Sometimes, especially in the scarlatiniform variety, it may have entirely disappeared in twenty-four hours. Other eruptions may last for weeks and months, changing their type repeatedly. The temperature may or may not be raised, and the form of the eruption has no direct relation with the height of the temperature. The eruptions almost always appear in the acute stage of the affection, or, in long-standing chronic cases, in the acute exacerbations. There is almost always some metastatic complication, most frequently implication of the joints, while in a good number there are endo- and peri-carditis and occasionally nephritis. In two cases there was enlargement of the spleen.

With regard to the pathogenesis of these eruptions, it is important at the start to exclude those affections that surely do not belong directly to the gonorrheal process. These are the secondary infections, where septic lesions are caused by the penetration of other micro-organisms in the mucous membrane that has been violated by the gonorrheal affection. In this way septic lesions of the heart and joints are produced, and also possibly septic eruptions, such as are met with in other septic affections, in the form of scarlatinal and hemorrhagic rashes. These may be excluded, as well as the drug eruptions, especially those from copaiba, cubebs and salicylic acid. In many individual cases it may be difficult to exclude the suspicion of a complication of some other affection with the gonorrhea, for example, erythema nodosum in the cases of this type. Yet their independence is regarded as far more probable. The view that these eruptions are to be regarded as reflex appearances produced by irritative processes in the genito-urinary organs is favored by the experiments of Lewin, who was able to produce the same appearances by irritating the urethra with a sound. Similar experiments undertaken by Buschke on his first and third case

failed to produce any result. He believes that these eruptions are produced by the introduction of the gonorrheal poison into the circulation. With regard to the further question, whether they are produced by the direct action of the gonococci on the skin or by that of a toxin, as is probable in so many other affections, the latter view is considered the more probable. It is not possible to demonstrate the gonococcus in the cutaneous lesions, and this parasite has only been found in the skin where there was a direct connection with the gonorrheal mucous membrane. Experimental investigations have, on the other hand, contributed to the view that the toxins and proteins of the gonococcus may produce inflammation, as shown by the studies of Wassermann, Schäffer and Christmas. Buschke concludes that the gonorrheal exanthemata stand in direct etiological relationship to the gonorrheal virus.

THIOSINAMIN SOAPS AND PLASTERS.

In 1892 H. v. Hebra[5] published the results of his observations on the treatment of lupus by subcutaneous injections of thiosinamin.[6] Apart from the distinct impression it made on the active lupous process, he recorded also its remarkable action on the scar tissue, either that produced by cauterization or from spontaneous ulceration of the lupus. Ectropion, caused by the destructive action of the lupous process about the eyelids, was completely healed, and scars about the neck transformed into a pliant tissue. Several patients were shown who had completely recovered motion in joints that had been immovable from the contraction of surrounding scars. Since then thiosinamin injections have been advocated and used in cases of scleroderma, scars and keloid with good results.

Unna, encouraged by these results, determined to try the local action of thiosinamin on the epidermis. The drug is insoluble in water and the alcoholic solution is quite painful when injected under the skin, and for this reason, perhaps, has been less often tried. Unna has used it both as a soap in 5, 10 and 20 per cent. strength, and in combination with his plaster muslins. These applications were compared with those previously used by him (massage combined with mercurial plaster, salicylic acid-plaster muslin, etc.), and found to be far more effective. The plaster proved much more effective and unirritating than the soap, and was tried with success in fibrous tumors of various kinds, keloids, leprous and syphilitic lesions, as well as in the scars from small-pox. In the latter case a mask of thiosinamin plaster muslin was worn during the night. Irritation and pain was not experienced from this method of application, as is the case with the injections. On parts of the body not covered with hair and protected by the clothing, a plaster worn permanently is most effective. On the face, hands and scalp it is better to use the soap, letting it dry on. In severe cases, affecting the face, the two methods may be combined, so that the plaster muslin is worn by night and the soap applied during the day. Thiosinamin soap may also be combined with former methods, such as massage and mercurial plasters, alternating the two procedures.

Unna alludes to the fact that practitioners generally regard the treatment of fibrous and cicatricial deformities as well-nigh hopeless, and while this attitude is not taken by the dermatologist, thiosinamin must be welcomed as a distinct advance in the therapeutics of this condition.

[6] Loc cit., Bd. xv, p. 337.

THE "PHOTOTHERAPY" OF LUPUS.

Dr. Stephen MacKenzie, who had recently returned from a visit to Finsen's Lysinstitut in Copenhagen, gives his impressions of this method in the *British Journal of Dermatology* for November, 1899. He was in daily attendance at the institute for a week and was given every opportunity for observation. He saw in this time a large number of cases that were under treatment, and also of cases previously treated that presented themselves for inspection. About 400 cases in all had been treated up to that time, the larger number during the last two years. MacKenzie says he has formed a favorable opinion of the light treatment. He admits that the results were less favorable where the lupus nodules were deeply seated, owing to the difficulty of penetration of the light and the necessity of prolonging the treatment. In cases where the nodules were superficial the results were very good.

Up to the time of his visit the light treatment had been applied to, besides the skin, the lips, gums, hard palate, tongue, septum of the nose and, guardedly, to the eyelids. Other local caustics and the electrocautery were also applied, and MacKenzie's admission that he was impressed with the importance of frequently employing local measures to the mucous membranes is not especially strong evidence in favor of the light method. The degree of inflammation excited by the light method varies much with the individual. Usually it is slight and causes no pain, but sometimes there are vesicles and bullæ, and the inflammation is much less from sunlight than from the arc light. When the inflammation is severe the treatment may have to be suspended for a time. It is asserted that erysipelas occurs in some cases under treatment just as it does in some cases of lupus not under treatment. MacKenzie says it is difficult to say very much about recurrences, but he saw cases where there had been no recurrence after the treatment had been discontinued for from one to two years. Upon the whole, MacKenzie's paper does not present very strong evidence of the superiority of the light method over others. It is not equally suitable for all cases, and radical surgical methods are often the best. He regards it as far better, however, than curetting or the application of caustics, and he considers that it destroys simply the bacilli, not affecting the diseased or healthy tissues. The objections are the great length of time required, on the average, a daily session of from three to four months, and sometimes as long as twelve months, the expense and the number of attendants necessary; but none of these objections seems to prevent the large influx of patients from all parts of Europe. MacKenzie was sufficiently impressed with this method of treatment to advise its adoption at the London Hospital.

PLAGUE IN MANILA. — Out of a total of 51 cases of suspected bubonic plague reported, 42 have proved genuine and 32 deaths have resulted, half of them being Chinamen. Sanitary regulations are being enforced through a large corps of inspectors, under the superintendence of a health officer. Thirty of the inspectors are Chinamen.

Reports of Societies.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT.

A. K. STONE, M.D., SECRETARY.

Regular meeting Monday, December 4, 1899, Dr. R. H. Fitz in the chair.

Dr. Charles S. Minot read a paper on

SCIENCE AND HEREDITY.

Robert MacDougall, Ph.D., read a paper on

PSYCHOLOGY AND HEREDITY.[1]

Dr. Putnam: I suppose all of us have but one feeling in regard to these very interesting addresses to which we have listened, namely, that we can add nothing to the illustration of the subject, but in what little we may say, express our appreciation of what we have heard. The physician, I think, whatever his branch of practice may be, is one to whom this question of heredity appeals perhaps more strongly than to any one in the community, in a practical sense, because to him the patient comes often with the spectre of a family disease in one or another form standing before him, and wishes to know what his chances are of falling a victim or escaping. If he can take a hopeful view the better the result of the influence he is likely to exert. From what we have heard to-night it seems to me all of us can take fresh courage, since the view is maintained, on the whole, that in spite of all the limitations that each individual brings into the world he comes in great measure untrammeled, and is at liberty, within certain limits, to develop as circumstances permit. It is evidently true from what has been said that acquired characteristics are not transmitted. The race moves slowly along, working out its tendencies, but a given individual, whatever his limitations may be, has a considerable chance of modifying his lot, a chance that perhaps his parents may not have had. The physician, it seems to me, stands as the guardian of the growing individual, and in great measure also as the person to whom the task falls of correcting the influences which society and environment exert. This enormous social force is being exerted all the time for good and evil, the physician appearing as go-between to recognize the possible beneficial influences and to make them more and more effective for good. Even the individuals whose power to develop is very limited because they are born as cranks or eccentrics of one or another sort may play a useful part. Although they may not be able to improve the race through their descendants, they can act in one or another direction to afford better opportunities for race development to reach their best goal.

Dr. Knapp: I think in spite of the doubt which has been cast as to the possibilities of inheritance of acquired traits, we must as physicians recognize that there is something with which we are dealing, which, although it may not be actually the inheritance of acquired traits in the ancestry, is still a most important and fundamental fact. I think, for example, few of us can view a family who are victims of Friedreich's disease, or muscular dystrophy, without feeling there is a most powerful influence at work there which as yet we cannot fully explain. Yet, although Dr. Minot has shown very clearly the evidence against the inheritance of acquired traits, we must recognize something which I think Dr. Minot would fully agree to, but which he did not dwell upon, namely, that certain influences affecting the general nutrition of the parent can have the most fatal effect upon the condition, later in life, of the child. Binswanger, for instance, who has presented the theory of Weissmann in its relation to nervous diseases most clearly and forcibly, has contended that the alteration in the germ plasma may be inherited or acquired by such conditions as chronic intoxication, infection, constitutional disease or local injury in the neighborhood of the generative organs and may thus lead to profound weakness in the offspring, which is interpreted later in life by some form of disease — often in the form of nervous or mental disease. The doctrine of heredity, therefore, may lose a certain amount of its force by the interpretation of Weissmann, yet it acquires a still greater force by showing the necessity which we are under of guarding against any deterioration of the vital force in the parent in order to prevent disease in the offspring. There is one more fact which seems to me wholly inconsistent with Dr. MacDougall's idea of bringing all the members of the community to a high degree of cultivation by the environment which is brought around them. I think we are surrounded by hundreds of dismal failures of that theory, the efforts which are constantly made in this and other communities to waste $5,000 educations on $5.00 boys. We must recognize it is wholly impossible to bring the individual to a high state of cultivation by his environment unless he has the structural qualities in the brain, which as yet we know nothing about, which are dependent in part upon the fetal nutrition, in part upon various nutritive and other conditions of infancy, and possibly in part upon conditions which he derives from his ancestors.

Dr. MacDougall: One remark in explanation of the statement which Dr. Knapp has questioned. What I had in mind was that practically no individual in the present kind of civilization that exists is able to live a primitive sort of life. He is surrounded with so much to develop him that he has to use appliances that others use and be presented with a vast amount of material which makes his life different from what would be led by the primitive man. It was in that regard I meant we brought them up to that mark.

BOSTON MEDICO-PSYCHOLOGICAL SOCIETY.

J. W. COURTNEY, M.D., SECRETARY.

(Concluded from No. 7, p. 166.)

Regular meeting at the University Club, Thursday, October 19, 1899, Dr. R. T. Edes in the chair.

Dr. Webber: I notice it has been said two or three times that no influence has been noticed upon the mental condition of the patient, but I should like to suggest that any agent which will assist sleep, improve the appetite and the nutrition, while not perhaps showing a direct effect upon the mental condition of the patient, is a powerful means towards recovery, and in that way the packs must favor the restoration to health, though the immediate effect may not be seen in the improved mental condition or sudden improvement. It seems to me that in a good many instances benefit is not obtained, because the packs

are applied only occasionally; they are not applied near enough together to obtain the continuous benefit and good effect from their application; but, if instead of using them at the time of the excitement and when the patient had passed that omitting the packs, if they had been used continuously, as Dr. Abbott used them in a good many of his cases, better results very likely would have been obtained. I have noticed very good results from the wet pack in some cases, not especially of mental disease; and I think we have in the means of hydrotherapy an agent that is of very great value. I have been very much interested in the paper, and am glad to know of the use of wet packs in the asylum. There is one question I would like to ask: whether the patients who have recovered have made any reference to the wet pack; and whether they speak of its benefits as though they were conscious of any good effects from this treatment.

DR. ABBOTT: I don't think any of them were asked about it, and I don't remember that they spoke of it at all. In none of the cases that recovered had the packs been continued very long.

DR. PAGE: We had a case at Danvers that had been pronounced a case of dementia, a young man, and I think he was troubled with constipation, and the family was very much interested in the case. They came to the hospital frequently, and in order to satisfy them I took additional interest in that case, and I thought I would try this girdle treatment and bring about the crisis as I explained a while ago. I remember that I ordered for that young man a girdle, or wet pack around the body, perhaps ten inches wide around his bowels, and that that should be freshly soaked in cold water as often as it got dry. The constipation was cured; and, by the way, I have seen several cases of constipation cured in that way. I believe that there were no ulcers produced in that case, but in a few weeks the mental condition of the young man improved and went on so rapidly that he went home, and his friends were of course very much gratified, because they had been assured by the officer of the hospital that there was no hope of his recovery, that he had passed into a state of dementia; and I remember their coming to me when he went away and I advised them to occasionally put on that girdle. I thought it might help out possibly in some way, and told them if he got excited or disturbed — he was an excitable young man — to try the cold water treatment in that way. Whether or not he has remained well I have no information, but he did not come back to the hospital, and as the family lived within five miles of the hospital I am sure he would have drifted back if his mind had become disordered again. I would like to say also, in addition, I have seen repeatedly the results of a daily blood count where the douche treatment was used, and there would be an increased number of red cells regularly from day to day. Of course they were not manufactured as rapidly as they would appear, but brought into the circulation from some source, and I was told that the experience in the German Hospital in Philadelphia and also that in New York with this douche upon cases of neurasthenia was more satisfactory than any other treatment that had ever been adopted by the physicians who had tried it there, and I think they still use it at the Vanderbilt Clinic and at the German Hospital. As Dr. Webber says, if you can be sure you are improving the metabolism and equalizing the circulation, you are doing all you can expect towards improving the mental condition, and if processes have not been set up beyond the reach of all medical help you ought to benefit them. I think Dr. Harrington is very much interested in this subject.

DR. HARRINGTON: I have been interested in this subject of hydrotherapy a long time, and some years ago while an assistant of Dr. Page in Danvers, we did something in that line in a crude sort of way, with some results. The douche-room which Dr. Page fitted up at Danvers two years ago for this purpose has been in constant use except when repairs were being made, and we have treated and are treating daily from 20 to 30 patients. The results in a general way are these: We have marked and rapid improvement in cases of alcoholism, particularly acute alcoholism; it seems to brace up the nervous system and the circulation better than anything else that I know of. And another class of cases in which we notice marked improvement, which has already been mentioned, are the anemias; they improve very rapidly, and the blood count shows the gain. Another class of cases are those in which there are vasomotor disturbances, where there are cold hands and feet and blueness of the extremities, where perhaps there is vasomotor paralysis. These cases will improve quite markedly and even with the first few applications there will be seen a change, marked change in circulation after the bath, but the unfavorable vasomotor condition may return again perhaps and will do so for days, but finally the nervous centres I believe are strengthened by this method of treatment. It is gratifying to know that these methods are being introduced and used more and are being more heard of and talked about by the medical profession. There is one thing that ought to be remembered, I think, and considerable stress laid upon it, namely, that water has its physiological action and its therapeutic indications just as much as any drug, and it cannot be used in any haphazard way and get the results that you wish to look for. At Danvers this past year we sent one of our physicians to New York, and he studied with Dr. Baruch and acquired all his methods and technique. Every case which now goes to the douche room for treatment is examined, that is, the record of the case is read by the physician and he sees what the physical examination was on admission, then he makes any further examination he may deem necessary, and every case is given a definite written prescription and the observations are made as carefully on every patient as time will allow. One thing that we observed as regards men and women, that men like the hydrotherapeutic treatment very much, but as a rule women do not; they object to it and we have to urge them oftentimes to go to the douche-room, and try to prevail upon them to do so, but still they object to it. With the apparatus we have to use water in a wide range of methods with varying temperatures and pressures and various forms of stream. I have not had a very extended experience with the cold pack personally, but I have seen instances in which motor excitement has seemed surely to be quieted and I was quite surprised that the doctor finds so many cases in which the same effect is reported. We had one case last winter which was very excited for days. The cold pack was tried persistently. This patient was also very much confused. The cold pack being used persistently in her case did seem to relieve her

mental confusion, at least her mental confusion cleared up a great deal and her motor excitement became markedly less. This case, however, did not recover. We have noticed very favorable results in insomnia during this past year by the use of sweaters, which Dr. Page alluded to. That is a very convenient method of applying a sort of cold pack.

Dr. Baldwin: In my private work I have had occasion to look after excited patients where there have been plenty of nurses, and where it has been necessary that there should be no restraint used to shock the feelings of the people at home. I have been for a number of years accustomed, when necessary, to use a wet pack for these patients. I have always been impressed with the wisdom of the man subject to attacks of depression, who, when he felt them coming on, used to draw a bath tub full of cold water and jump into it, and he remarked that he never came out with the same thoughts and feelings that he had when he went in. It seems to me aside from being a restraint that the wet pack, no matter how warm the sheets when you wring it out, acts in the same way, and it does have some effect to change the current of one's thoughts.

Dr. Bancroft: I should like to ask Dr. Harrington, who has apparently had some experience with the wet pack, and the more expensive and complicated apparatus as used now at Danvers, if he found any objection to patients taking the wet pack. I understand you met with a great deal of opposition from the women. We have tried the wet pack at Concord with the women almost exclusively and never found any objection from them to going into it, and yet you say they objected to the douche.

Dr. Harrington: They objected to going to the douche-room and taking the bath. I did not mean to be understood that they objected especially to the cold pack.

Dr. Bancroft: My experience has been that they rather liked it.

Dr. Harrington: We hear wails every day when the women come back from the douche-room, and they often beg not to be sent again.

Dr. Bancroft: It occurred to me whether it was not an argument in favor of the wet pack if the patients object to the more expensive apparatus and do not object to the wet pack; it is a question in my mind whether we do not get the same beneficial effects from the cheaper old-fashioned method of the sheet wrung out in cold water.

Dr. Harrington: You undoubtedly can get the therapeutic effects from various ways without any apparatus except sheets and blankets, bath tub and tin dippers.

Dr. Page: I have seen patients in covered bath tubs in England and I thought it was the most forbidding form of restraint ever devised. I am told by Dr. Clouston, of Edinburgh, they have not employed this method for many years, since they had two persons die in the tub, probably owing to the fact that the water was allowed to get too warm and the patients fainted away. They were locked in like a person in the stocks. There was a big board over the bath tub, the neck fitting in the hole through the board.

Dr. Worcester: There was considerable stir made in England, I think some two years ago, about a case in which a patient was kept in a wet pack for twenty-four hours, or more, continuously for disciplinary purposes and died in it. It was in some private asylum.

Dr. Page: This restraint was in the Holway Asylum. When I was there I saw a woman in the tub who begged me piteously to let her out and I wanted to do so, but the superintendent was with me and I didn't dare to. That was the hospital where a patient died subsequently in a pack, and an investigation was held by the commissioner of lunacy.

Dr. Abbott: The prolonged baths I think are now used in Heidelberg and the cases in which they get most benefit are those of the maniacal phase of manic-depressive insanity; it is those cases in which we have had the best therapeutic results at Northampton.

In regard to the duration of packs, Dr. Page has spoken of not continuing them so long as three hours. Apart from the fact that patients are under constant observation for unfavorable symptoms, and none are found even after a pack has been continued four or five hours, provided it has been properly given, one investigator has found that after about two and a half to three hours there is evidence that toxins are eliminated; that is, the fluid wrung out from the sheets with which the patients have been wrapped is found to be toxic for small animals. Whether those results have been confirmed by further investigations I don't know If packs are taken off at the end of an hour patients sometimes have to be wakened out of a sleep to remove them. The patients feel comfortable if the pack is properly applied, for so long a time as it has been thought best to continue them. These facts justify a prolonged application, even to four or five hours.

Whether the pack should lead up to colder applications, as Dr. Putnam suggests, depends partly upon the object to be accomplished by it. In most of the cases reported it was used for its quieting effect, and a brisk rubbing down after the pack to bring the glow to the skin was considered sufficient. If the pack had been given for the tonic effect on nutrition we should have given it for a shorter time and followed it by cold applications.

The first case of general paralysis on which we tried the wet packs at the McLean Hospital was one of such rapid exhaustion from refusal of food and constant activity and resistance that an almost certainly fatal result within twenty-four hours was predicted. A similar case, in which packs had not been tried, however, had died not long before, and that must be the one Dr. Tuttle has in mind. Packs were given and the patient began to eat at once; he improved from the very hour the first pack was applied. So with one of these cases of paresis on which they were tried at Northampton, only there they were not continued more than ten days, the immediate urgency having been relieved.

That the packs have more than a moral disciplinary effect and more than enhance the influence of the physician is shown by the fact that very few of these patients on whom we tried the packs would be as quiet three hours after restraint by camisole or being held by nurses as they are three hours after the pack; they would have been very much more resentful of such restraint and probably would have begun right away to use violence again. There is something more than moral effect, and it is this fact that justifies its use in these cases of excitement.

We cannot yet say that because nutrition, etc., are

improved by the packs they therefore exercise a curative effect on the psychosis. For example, in a chronic case of eight or ten years' standing that has violent outbreaks the latter may be markedly diminished and nutrition may be improved, but the psychosis is still there, delusions still persist, and there is no expectation that the patient will recover. It will be rather in the acute cases, like the maniacal phases of manic-depressive insanity or acute stages of dementia precox, that most benefit is to be expected.

A special room for hydrotherapeutic measures is desirable and even necessary for some modes of treatment, but I think it is a great advantage to have such simple measures that they can be used in the room where the patient is, rather than have the patient taken to another ward or another room. Where such measures are used as a means of introducing variety into the life of the patient there is a distinct indication for a special place, and many kinds of apparatus require a special room; but some of the results obtained by such expensive apparatus can also be secured by the use of the pack, which can be applied in any place without special apparatus. It is to these that I wished to call attention.

Recent Literature.

A Text-Book of Materia Medica, Therapeutics and Pharmacology. By GEORGE FRANK BUTLER, Ph.G., M.D., Professor of Materia Medica and Clinical Medicine in the College of Physicians and Surgeons, Medical Department of the University of Illinois, etc. Third edition, thoroughly revised. Philadelphia: W. B. Saunders. 1899.

A third edition in three years is proof that a book has merits and fills a need. The present volume contains 826 pages, excluding the indices. Following the introduction are definitions of pharmacology and therapeutics, with sections on the classification and administration of medicines, the untoward effects of drugs, and weights and measures.

Pharmaceutical preparations occupy some 80 pages. It seems to us a mistake to devote so much attention to this branch of the subject, especially in this instance, because the writer furnishes all and more than is needed for the student in his discussion of the individual drugs. As an example of this is iron, which consumes by the enumeration of its preparations more than 10 pages! Surely the sins of our forefathers are visited upon us. The therapeutics of to-day is simpler than ever, because it rests on a more rational basis. Why not give the student the benefit and write a simple book?

The drugs are divided into "disease medicines" and "symptom medicines"—a classification rather more unsatisfactory than usual. Why bitters should be considered disease medicine is hard to see.

Twenty-eight pages at the end of the book are devoted to prescription writing. It is certainly a sad commentary on the requirements for admission to our medical schools that it is deemed necessary by the author to decline "oliva" and "fluidus" in full.

The account of serum therapy is good. On page 144 hydrochloric acid is recommended for atonic dyspepsia; on page 164 alkalies are advised for the same condition. How much more advantage students would derive from a résumé of gastric treatment based on the study of the secretions and the motility of the stomach than from these loose statements.

It is unfortunate that students also must learn the following: "The diluted hydrochloric acid is a valuable (!) internal remedy in the treatment of diphtheria, and during the course of fevers, particularly typhoid. As a routine treatment in the latter disease the author almost invariably gives hydrochloric acid in connection with pepsin, finding that it not only allays thirst and moistens the tongue, but exerts an antiseptic influence in the bowels (?), thereby lessening the danger of autoinfection(!?) and relapse (!?)."

There are some good things in the book, but the author owes it to his readers to rewrite much of the text.

The American Year-Book of Medicine and Surgery. Being a Yearly Digest of Scientific Progress and Authoritative Opinion in all Branches of Medicine and Surgery, drawn from Journals, Monographs and Text-Books of the Leading American and Foreign Authors and Investigators. Collected and arranged, with critical editorial comments, under the editorial charge of GEORGE M. GOULD, M.D. Philadelphia: W. B. Saunders. 1900.

This well-known Year-Book is issued this year for the first time in two volumes, one on medicine, the other on surgery, without increase in cost. Each volume may be had separately if desired. The constant increase in medical literature has made this change necessary. The previous single volumes of this work already contained from 1,100 to 1,200 pages and were becoming unwieldy. These two volumes contain a little over 1,200 pages. The volume on medicine has about 100 pages more than the volume on surgery. Each volume has its own index.

The medical volume is divided into General Medicine, Pediatrics, Pathology, Nervous and Mental Diseases, Cutaneous Medicine, Materia Medica, Physiology and Legal Medicine, Hygiene, Chemistry, etc.

The surgical volume embraces General Surgery, Obstetrics, Gynecology, Orthopedic Surgery, Ophthalmology, Otology, Larynology, Rhinology and Anatomy.

Some changes have been made in the editorial staff. Dr. Gould now has fifteen collaborators, among whom the different departments are divided up. The work as a whole is well and carefully done, the paper and type are excellent, and such illustrations as are given are good. There has been no effort to make it a picture-book.

These volumes would be a valuable addition to the physician's library.

MEMORIAL TO J. W. STICKLER, JR., M.D.—Mr. and Mrs. Joseph W. Stickler, of Orange, N. J., have offered $40,000 to the Young Men's Christian Association of that city, for the erection of a new building as an additional memorial to their son, Dr. J. W. Stickler, Jr., who died last year, and who was the first president of the association. Plans of the memorial library building which, as previously announced, Mr. and Mrs. Stickler are to erect at a cost of $40,000, have now been completed, and one of the rooms in it is to be devoted to the medical library of the deceased physician, for the use of medical students. Dr. Stickler's entire laboratory apparatus has been given by his widow to the Orange Memorial Hospital.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, FEBRUARY 22, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

ANNUAL REPORT OF HARVARD UNIVERSITY.

As is natural, these reports grow in bulk with the growth of the University and this increase has of recent years been considerable. According to our usual custom, we shall try to pick out those points having an especial interest for the medical profession. The President tells us that "the common attainment of the degree of Bachelor of Arts in three years is certainly approaching. No specific legislation will be needed to accomplish this important change; for any young man of fair abilities can now procure the degree in three years without hurry or overwork, if he wishes to do so, or if his parents wish to have him. That this wish is felt by an increasing number of students and parents is demonstrable. . . . Within a time, comparatively short, the majority of those who enter the freshman class will come to college with the purpose of completing the requirements for the degree in three years. A large number of the present freshman class have already avowed that intention, and made their choice of studies accordingly." Anatomy, physiology and hygiene are now among the studies which may be presented in satisfaction of the requirements for admission to Harvard College. Putting these statements together, one sees some prospect of reconciling the possession of an A.B. degree with the increasing demands of the professional schools, and the possibility of entering upon an active career in the learned professions — these including to-day more than the three of our fathers — at a period of manhood not too advanced. All this is of especial interest to those seeking a medical training, the demands of which are now so exacting.

The extraordinarily low death-rate reported by the Dean of the College in successive years is very striking, and tends, as the President states, to show that college students are in reality a picked body of youth, physically, as well as mentally and morally. In the year 1895–96 four died out of 1,772; in 1896–97 four out of 1,754; in 1897–98 four out of 1,819, and in the year 1898–99 three out of 1,851.

The function of the medical visitor is now established as a regular part of the college system, and tables are given showing the nature of the diseases which prevailed among the students in Cambridge in each month of the year and the number of days of illness in each month. The President believes that this office not only secures for the sick student earlier and better treatment than he would otherwise have, but also prevents serious sickness by providing the ignorant student who works to excess, drinks too much tea and coffee, sleeps too little, eats too much, or takes no exercise, with wholesome advice in good season. Dr. G. W. Fitz, who filled this office, did not desire reappointment at the end of his five years' service as an assistant professor last September.

In connection with this office of medical visitor and the duties inherent to it, we note the President's announcement of an endowment from an anonymous source of $156,000, for the establishment of a professorship of hygiene; the object of the giver being "to provide the students of Harvard College with a medical friend competent to give them the best advice, winning in his nature, and devoting himself chiefly to the physical and moral welfare of the undergraduates at Cambridge. . . . He is not to be a teacher in the ordinary sense of the term, though he may lecture, and he is not to be professionally connected with the Medical School, though he will be free to undertake hospital service; neither should he have so much practice, whether in consultation or otherwise, that his attention should be much diverted from the body of undergraduates, and inasmuch as his salary under these conditions will be the greater part of his income, the giver of the fund desires that it accumulate until it yield a liberal salary, sufficient to attract to the position a man of high quality."

"This gift," the President remarks, "is one of the most interesting which the University has lately received, and one likely to do much good, first, by informing the prevailing ignorance concerning the means of bodily health; secondly, by checking or preventing reckless exposure to moral and physical evils, and thirdly, by arresting incipient injury through wise and seasonable advice."

The following extract is given from the agreement in regard to this professorship of hygiene:

"To apply the said fund so soon as the income thereof shall be large enough in the judgment of said Corporation for a permanent foundation for the liberal maintenance in the undergraduate department of said College of a full professorship of hygiene.

"The holder of such professorship shall be a regularly educated physician of marked ability and industry and of a temperament likely to enable him to elicit readily the confidence of young men. His duty shall include an earnest personal interest in the physical welfare of the undergraduates and an intimate personal intercourse with them so far as this can be had without officiousness on his part, to the end that he may proffer advice in a spirit of friendliness and be easily approached by such of them as desire his counsel.

"It shall be the duty of the professor, both by advice and by personal interest, to encourage especially open-air exercise and sports, and to take a particular care that undergraduates of sedentary and studious habits be made acquainted with the importance of physical recreation."

The importance now attributed to this sort of academic supervision is well illustrated by the recent discussion as to its birthplace among the colleges, just as the cities of Greece disputed the honor of the birthplace of Homer.

We have elsewhere and previously considered most of the especial points in this report having reference to the Medical School. In regard to one of the most important changes the President says:

"The results of the experiment of massing all the lectures and laboratory exercises in a fundamental subject into a half-year, and keeping the whole time of the student during that period occupied with two subjects will be of interest not only in the Medical Department, but in many other departments of the University. The preliminary work in preparing this plan was done by a committee of the Medical Faculty called the Committee on Medical Education, and the same Committee has under consideration a rearrangement of the work of the third and fourth years. The changes in the programme of the first two years have already gone into effect, and are giving great satisfaction." A definite judgment upon this experiment can hardly be passed until the results of the second examinations in the studies of the first years have been determined.

There has been an increase during the last five years in the percentage of college graduates among the new matriculants of the school; but in the year under review the percentage of new matriculants who held a degree in arts, letters or science was only 42.66 per cent. After the current year, the entering class is to be composed exclusively of college or scientific school graduates.

Notwithstanding numerous changes in the interior of its present building, the Medical School urgently needs more lecture room and more laboratory room. This need must either be met radically by moving the whole school to some other site and erecting new buildings, or temporarily by finding accommodation for some departments outside the present buildings.

The Dental School, though prosperous, and, partly because it is prosperous, having an income exceeding its expenses, is in the same position with regard to its home. The difficulty here is increased by the fact that the Dental School does not own its building and the building is liable to be sold. All this means money and a good deal of it.

The close connection between the Dental School and the Medical School, at least during the first year of instruction, makes it important, the President thinks, that when a new building can be erected for the Dental School it should be placed close to the Medical School, or at least close to that part of the Medical School in which the instruction of the first year is given. On the other hand, for the sake of patients for clinical instruction, it is very important for the Dental School to be in the centre of a populous neighborhood.

The Corporation during the year determined on another large use of the Pierce bequest — this time for the promotion of instruction in comparative medicine, but in three separate sums, $100,000 as the foundation of a new professorship to bear his name, $100,000 for a medical laboratory building to bear his name, and $100,000 as an endowment for the laboratory. The details of this appropriation await the advice of the Faculty of Medicine. The ultimate disposition of the Calvin Ellis bequest apparently still remains to be determined.

As a matter of some general interest, we note that the Corporation has voted that it is not prepared to admit women to the instruction of the Law School.

MUD AND DUST IN WINTER.

AN occasional snow-storm should not, in the least, abate our interest in the question of dust and its menace to health, which has of late particularly agitated this community. Experience has shown that a considerable part of the New England winter is likely to be without sufficient snow to prevent the accumulation and dissemination of dust. In spite of the comparatively heavy fall of snow we have just experienced, the irrepressible dust has still actually on the same day been much in evidence on one of the main streets of this city, due merely to the fact that after the snow was blown off a certain area of the street, the underlying dust found again its opportunity. Whatever the final remedy for the nuisance may prove to be, it is sufficiently evident that we cannot depend upon the caprices of the weather alone, in the shape of opportune rain or snow storms. We must find some means of actually getting rid of the dust, and of the conditions which make possible its accumulation.

Clearly we are not alone in our faultfinding, for in a current issue of our contemporary the *Medical Press*, a vigorous protest is raised against mud as the progenitor of dust, and hence equally to be avoided. Thankful as we should have been during the last months for mud in any amount, we should not forget, as our contemporary points out, that mud always represents the possibility of dust, and that our watering carts in summer and our rains or snows in winter are merely palliative and not curative. We should in some way get at the source of the difficulty by insisting on absolutely clean streets. In the meantime the following suggestions of the *Medical Press* are apt and interesting:

"The part played by mud in the hidden and various ways of disease production will doubtless be one day laid bare by some curious apostle of science. Meanwhile there are certain points about mud that

are clear to the man in the street. Its distribution by the splash of passing vehicles covers a much wider field than folk usually recognize. Spots of mud thus projected may often be seen adhering to house-fronts at a height of several feet above the top of the ground-floor windows. Dry mud, be it remembered, is on the way to become dust, to be blown hither and thither with its host of microbes, good, bad and indifferent. 'The bacteriology of street mud'— who will undertake that investigation, laborious, well-nigh boundless, fascinating, complexly baffling, and yet fraught with vast potentialities for the good of man. The average citizen, however, knows little and cares less for the bugbears of bacteriology; he is more concerned for the safety of his clean collar, the polish of his silk hat, the sheen of his shoes, and the untarnished splendor of his raiment beneath the spatterings of a muddy day in the city. Where the mud comes from is a mystery in the case of smooth impermeable pavements. It is certainly greatly lessened in amount when asphalt, concrete, or wooden roadways replace the time-honored macadam. Judging from the signs of the times, it seems likely that in a not distant future sanitary authorities will learn to take a deep interest in the matter of city mud in relation to the public health."

To those of us who have taken the trouble to watch the methods of the city employé in his street-cleaning attempt, it is not difficult to see why we still have mud and therefore dust. After a rain-storm, for example, a small army of men may be seen scraping a portion of the mud into small piles, which are then in part thrown into carts. From the remainder dust is made which again is heaped by nonchalant workmen into piles, which in turn, if any wind be blowing, are thrown rather into the surrounding air than into the carts ready to receive them. In short, quite apart from the question of pavement, our streets are not properly cleaned. We certainly need better pavements, but we also require a consistent and painstaking effort on the part of the authorities to take measures, clearly within their power, toward the furtherance of adequate street cleaning.

CASES OF RASH AFTER ENEMATA.

In the *Glasgow Medical Journal* for September, 1899, Dr. T. K. Monro, of Glasgow, calls attention to the fact that, although the observation is not new, it is true that cutaneous eruptions may be produced by enemata, and that this has escaped mention in most dermatological text-books. The writer thinks that this eruption has often been wrongly attributed to a surgical operation or to an anesthetic, and that some cases of so-called surgical and puerperal scarlatina are due to enemata. Also many cases have been attributed to the action of drugs that really belong in this class.

All the cases that the writer has been able to collect are in the English language, and all but one are found in British literature. In only one case, that of a boy of eleven years, was a male affected; in 26 others besides the six reported by him, the patients were females. Burford and Gardner, who have published the largest number of cases, were gynecologists. Three of the cases were in patients suffering from gastric ulcer. Habitual constipation seems to be a condition common to the greater number of cases, and to account for the greater prevalence in the female sex. The eruption may occur in patients who have previously used enemata without any such effect, and subsequent enemata may or may not act in the same way. Usually the interval between the injection and the appearance of the eruption is about twelve hours, but it may be as long as twenty-four, or as short as two hours, and the eruption's average duration is two or three days. In type the eruption is either scarlatiniform, morbilliform, or urticarial of the small type. Occasionally, these forms may be combined. The seats of predilection are the buttocks and thighs, and the face, but any portion of the body may be invaded. Slight changes in the temperature and in the pulse have been noticed, and occasionally there is redness of the tongue and fauces. Constitutional symptoms are usually wanting. There may be considerable burning and itching. The eruption occurs only after enemata of large size, never after glycerine or nutrient enemata.

It has been generally assumed that the cause of the eruption is fecal absorption, which is partly excreted by the skin and causes the rash. Morgan, in 1895, suggested that it was due to a particular kind of soap, and Gardner, that it was often produced by the use of hard yellow soap. Others have stated that the eruption follows three to four per cent. of the enemata, and that it is common also after a strong aperient in chronic constipation. The writer asserts that experience has shown that soft and not hard soaps ought to be used in enemata. Six new cases are described.

In the first case, that of a woman of twenty-five, who was being treated for hemorrhage from gastric ulcer, the patient had had for about a week before the appearance of the rash nutrient suppositories, and enemata of milk, eggs and beef tea. She had also had laxative enemata of soap and warm water, and, on one occasion, of castor oil every two or three days. Dilute hydrocyanic acid and chloroform water were the only drugs employed. The eruption was an erythema not sharply bounded, in some places distinctly elevated, affecting the face very slightly, well marked on the right upper arm and forearm and on the thighs, slight on the hands and legs.

In the second case, that of a woman of twenty-two, an eruption of a morbilliform character appeared about twenty-four hours after an enema of soap and water. The eruption was very pruritic, and was most marked on the trunk, although later it was actively present on the arms and legs. It is admitted that in this case the administration of chlorodyne at the same time as the enema renders the etiology somewhat doubtful.

In the third case, the day after several enemata of

soap and water had been given for pain in the bowels, there appeared a diffuse erythema of the face and hand. Morphia had been given hypodermatically the night before the eruption appeared.

The fourth case was that of a governess, who had after an enema (and the administration of chloroform) a general scarlatiniform eruption accompanied by fever. There was some redness of the fauces, but the tongue was not characteristic of scarlet fever. At the end of three days, when the patient was last seen, the eruption had practically gone from the extremities, but was well marked on the hips and thigh.

In the fifth case, a woman of twenty-two was in the beginning of her second week of typhoid fever. Twelve hours after an enema of hot water with soap and castor oil she was awakened by itching of the arms, neck and face, and the next morning there was a pretty general urticaria present. The same result followed a second enema, while a third one was not succeeded by any eruption. This patient had previously used enemata of soap and water without any cutaneous disturbance.

The last case, one of gastric ulcer, developed an itchy, papular eruption on the face, hands and thighs, a few hours after an enema of water, soap and castor oil. This eruption extended rapidly over the whole body. A second enema a few days later was followed by the same appearances.

THE LIMIT IS REACHED.

WE have long looked somewhat askance at the growing tendency toward the coining of new medical terms. The unfortunate gall-bladder and liver region has suffered most severely at the hands of the anastomosing and resecting surgeon, who has seen fit to burden with a new name each new operation. We stoutly maintain, however, that the limit has been reached when such words as the following are thrust upon us. A distinguished surgeon writes, "I report this case because it suggested a new operation, hepaticocholecystostcholecystenterostomy, or hepaticocholecystostenterostomy." If our opinion were asked we should choose the second alternative, since it comprises thirty-one instead of forty letters, but we should much prefer to be spared either, even granting the necessity of a slight circumlocution in arriving at the meaning. When a word is unpronounceable it should be inadmissible in any well organized language, and these, we urge, are pronounceable, if at all, only after strenuous practice. Let us at least stop here.

MEDICAL NOTES.

STATISTICS REGARDING ILLNESS AT HARVARD UNIVERSITY. — We learn that objection has been made to a note published in our issue of January 25th, on "Illness at Harvard University during the year 1898–99." After quoting certain facts we said, "The value of statistics of this sort is not altogether apparent." Our meaning naturally was that from a medical standpoint such statistics are of small value, owing to the relative fewness of the observations, and to the method of classification used. We are now informed that the analysis of the students' illness has been made solely for the purpose of determining Harvard's need of an infirmary and of making that need definite. We are completely in sympathy with all efforts toward the establishment of such an infirmary, as previously indicated in our editorial columns, and have no desire to criticise means directed to that end.

PRACTICAL GUIDE TO THE DESTRUCTION OF MOSQUITOES.—The Liverpool School of Tropical Diseases, according to the *British Medical Journal*, has just issued a pamphlet entitled "Instructions for the Prevention of Malarial Fever for the Use of Residents in Malarious Places." Within the compass of fourteen pages it sets forth in concise terms which cannot fail to be understood facts of practical importance concerning the parasitic nature of malarial infection, its connection with a special kind of mosquito, and the means which hold out the best hopes of ridding a house or a neighborhood of these insects and of the malaria which they are believed to convey.

LAWS REGARDING TUBERCULIN. — Illinois farmers and stockmen are agitating changes in the laws regarding the tuberculin test for tuberculosis in cattle, and their compulsory enforcement. A report which was recently submitted at a mass meeting in Chicago summed up all the disadvantages of the tuberculin test as it is at present applied. The report was adopted and also a resolution to the effect that the chairman of the meeting appoint a standing committee of five, to whom all facts, experiences and complaints with reference to tuberculosis in cattle might be communicated.

YELLOW FEVER ON SANTOS STEAMER. — It is reported that a steamer recently arrived in New York from Santos had on board two cases of yellow fever during the voyage. A fireman died of the disease and was buried at sea, and the other has been removed to an isolation hospital. The vessel's cargo is being held, subject to action by the health authorities.

STATISTICS FROM PUERTO RICO. — The consolidated report of the Board of Charities of Puerto Rico, for the week ending January 27, 1900, gives the following statistics: The total population of the island is 956,779. Of these 80,642 are classed as indigent; 3,857 as sick; 669,425 rations were issued, and 9,076 men were working for food alone.

INSANE SOLDIERS.— During the last three months it is reported that nearly 250 soldiers with mental disease have been sent across the continent, and it is said that over 200 more will soon arrive at San Francisco from Manila. In nearly all cases the men are said to be violently insane.

A LAW REGARDING ICE. — Acting on the advice of the Council of Hygiene, the prefect of police in

Paris, it is said, has decided that ice sellers must sell ice of two definitely distinct kinds. These must be ticketed as ice for eating purposes and ice for industrial purposes, the former being obtained from spring or sterilized water.

Havana Board of Health. — An Havana Board of Health, consisting of six Cuban physicians, has been organized by General Ludlow. The chief surgeon and chief sanitary officer of the Department of Havana are members *ex officio* of the Board.

Sir Michael Foster, M. P. — Sir Michael Foster has been elected as an Independent Unionist, by a very handsome vote, to represent the University of London in Parliament. He replaces Sir John Lubbock, who was a Liberal Unionist.

Hospital Ship "Missouri." — The hospital ship *Missouri*, now in service in the Pacific, is said to be both unseaworthy and unsanitary. An investigation into the condition of the vessel will be made.

Bequest to a Hospital. — It is reported that James Walker, of Wilmington, N. C., is to provide the City Hospital of that city with a building to cost $30,000.

BOSTON AND NEW ENGLAND.

Acute Infectious Diseases in Boston. — For the six days ending at noon, February 20, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 93, scarlatina 38, measles 61, typhoid fever 3.

Vaccination in Connecticut; Death Certificates. — According to the Bulletin of the Connecticut State Board of Health, Connecticut has been remarkably exempt from small-pox in view of its widespread prevalence in many other States. This is attributed to vaccination, which is more general in this State than in most other States, although it is not compulsory. Since the Bulletin was issued, Dr. Lindsley, Secretary of the Board of Health, has had letters from town health officers, stating that in their respective towns vaccination had been of late years much neglected. He points out the possible dangers of an epidemic in those towns and says: "Vaccination is a public duty for the protection of the whole community, as well as a private obligation for self-preservation, which none have the right to neglect." Dr. Lindsley further writes in this report that the new form of death certificates has blank spaces after the words year, month and day, to give the exact date of death. Of course the blundering genius has seized his opportunity. It is astonishing to what extent human ingenuity can invent wrong ways of filling out a blank form of certificate. This time the blunderer completely defeats the purpose of the certificate by writing the day of the week instead of the day of the month, thus: Year, 1900; month, January; day, Tuesday. Query, which Tuesday? There were five in January. Registrars who issue burial permits on such certificates, and there are several of them, ought to have their names published in the *Journal of Statistics*.

The Willard Hospital. — It was one of the wishes of Miss Frances Willard to establish a hospital for the care and treatment of dipsomania. After careful deliberation a corporation has been formed under the laws of Massachusetts, to be known as the Willard Hospital Corporation. A country place having suitable buildings and extensive grounds with pleasant surroundings, located within fifteen miles of Boston, has been selected, and the directors are now endeavoring to raise the necessary funds to establish and maintain such an institution.

Medford Schools Reopen. — The Tufts and Lincoln Schools in South Medford have been reopened, after being closed for two weeks on account of the prevalence of diphtheria and scarlet fever. Since the schools were closed the buildings have been thoroughly fumigated and the plumbing carefully overhauled. The books which were used by children who have since been ill with scarlet fever or diphtheria have been burned.

The Sharon Sanitarium. — A performance was given February 15th at the Tremont Theatre for the benefit of the Sharon Sanitarium, in which various well-known actors and actresses took part, among whom were Mrs. Agnes Booth-Schoeffel and John Drew.

Hospital for Peabody, Mass. — Land has been purchased in Peabody, for the purpose of establishing a hospital. The tract comprises 114,500 square feet.

NEW YORK.

Award of Prizes, Tenement House Exhibition. — The jury of award in the prize competition at the Tenement House Exhibition, in assigning the award in the case of the third prize for tenement house plans, found that three of the plans submitted were of equal merit, and as the amount of this prize was but $100, a purse of $225 was made up, to be divided equally among the three competitors. It is stated that the committee of the Charity Organization Society having charge of the exhibition has already received offers from builders to construct several buildings after the best plans submitted. One of the notable models exhibited represents in miniature the most populous block in New York, between 61st and 62d Streets, on the west side of the city, where 4,000 human beings live. Of the 2,639 rooms in the houses, only 1,198 have windows facing the outer air, and there is not a bath tub in the block.

Annual Report, Manhattan Eye and Ear Hospital. — The thirtieth annual report of the Board of Directors of the Manhattan Eye and Ear Hospital states that during the past year 1,407 applicants were refused treatment because it appeared that they ought to pay. For some time past doubtful cases have been referred to the Charity Organization Society for investigation, and during the year 120 cases were so re-

ferred. An extract from the law having for its object the correction of the abuse of medical charity which was passed by the Legislature last year is now printed on the back of each card, so that no one applying at the hospital can claim ignorance of the law. The report states that the C. R. Agnew Memorial Fund now amounts to $21,217, and that $5,000 has been received from Miss Helen Gould for the endowment of a free bed.

THE OFFICE OF CORONER. — At a meeting of the Society of Medical Jurisprudence held February 12th, Dr. Hamilton Williams read a paper on "The Coroner's Physician at Work," in the course of which he argued against the abolition of the coroner's office. Drs. Donlin and Weston, also coroner's physicians, spoke of the onerous and exacting work and the inadequate payment of the position. They thought that the number of coroners' physicians should be increased. At present there are but four for the entire Borough of Manhattan, and they believed that there should be one for every 200,000 of the population. Dr. H. R. Purdy spoke strongly in favor of doing away with the coroner's office, expressing the opinion that the work now done by the latter could be better accomplished by experts appointed by the Board of Health.

ANNUAL REPORT, DEMILT DISPENSARY. — In the forty-ninth annual report of the Demilt Dispensary it is stated that the success of the dispensary baths for working people, which increased from 17,089 in 1897 to 37,236 in 1899, has been a source of gratification to the managers, the baths having proved a great boon to many persons who have no bathing facilities whatever in their tenements and who gladly avail themselves of the benefits offered.

Miscellany.

A MODEL TENEMENT HOUSE EXHIBITION.

A MODEL tenement house exhibition, which is to last for two weeks, under the auspices of the Tenement House Committee of the Charity Organization Society, was opened on February 10th, with addresses by Frederick W. Holls, Chairman of the Committee, Governor Roosevelt, Dr. E. R. L. Gould and others. Over three hundred plans of model tenements have been submitted by architects in competition for the prizes offered, and the exhibition includes models, plans, maps, charts and tables of statistics, showing existing conditions in New York tenement houses, model tenements in various cities of the world, lodging houses, suburban dwellings for the poor, health conditions, poverty conditions, and agencies for betterment. According to the statement of the Committee, there are at present over 44,000 tenements within the limits of the old city of New York (prior to the consolidation of 1898), and new tenements are now being erected at the rate of about 2,000 a year. These are, in many respects, worse than the old buildings erected thirty years ago. They are, in some instances, badly constructed, and so planned that many rooms depend for their light and air entirely upon long, narrow, dark "air shafts," which, instead of giving light and air, are merely stagnant wells, emitting foul odors and disease. Under the present law, the Committee states, in a block covered with flat houses only 10 feet need be left open in the rear of each lot, and a like 10 feet on the rear of the lot on the next street would give a space of but 20 feet for both rows of houses. The other 15 per cent. of area required to be left open by the law is taken up in the space allowed for the air shaft, which is usually five feet wide and about 60 feet long, closed at both ends; and this dismal, Egyptian-like well hole must, if the apartment houses be five stories in height, as the majority are, furnish light and air to 50 inside rooms, usually used as sleeping apartments. A marked contrast to this condition of affairs is presented by the Riverside model tenements, which are so constructed that in the centre of the blocks are large courts measuring 150 by 250 feet, which are fitted up as playgrounds for the children. All the rooms are well supplied with light and air, and in the Riverside Court a band plays on summer evenings. Notwithstanding all the expenditure, the owner is realizing five per cent. on his investment. In his remarks the Governor gave assurance that any bills having for their object the betterment of existing conditions in the homes of the working classes would meet with hearty co-operation at Albany, and Dr. Gould, who is president of the City and Suburban Homes Company, in speaking upon the commercial side of the question, showed that model tenements pay from four and one-half to six and seven per cent. on the money invested.

A LECTURE ON SURGICAL SPLINTING.

ON Wednesday, February 14th, a clinical lecture on the subject of "Surgical Splinting" was delivered by Dr. Edward A. Tracy, of Boston, before the New York School of Clinical Medicine. The lecturer treated his subject from a purely practical point of view, and illustrated by demonstration a method of splinting found advantageous in the treatment of fractures and joint injuries and diseases. The use of manufactured splints was condemned, they being but a poor makeshift for the skill which the surgeon should have at his fingers' end. Such splints require padding and this renders nugatory their fixative properties. Normal limbs are not alike, and the idea of making them conform to the shape of a ready-made splint is not surgical.

A word was spoken about the plaster-of-Paris treatment of fractures, and it was urged that when this method be employed the necessary care should be taken to prevent its harmful results, so frequently manifest in practice from lack of such precautions.

The lecturer devoted considerable time to describing the method of moulding splints directly upon the patient, and emphasized the use of wood-plastic material for the purpose. Its advantages are its strength, porosity, lightness, durability and cheapness. Four easily constructed splints were described, a splint for the wrist, one for the shoulder, one for fixation of the knee-joint, and one for leg fractures. When speaking of the wrist splint he referred to its important use in the treatment of Colles's fracture. The subject of Colles's fracture was enlarged upon and the desirability of following Moullin's advice to practise early passive motion of the fingers and wrist-joint insisted upon.

A PLAGUE LABORATORY.

THE St. Petersburg Institute of Experimental Medicine has, according to the *Medical Press*, just completed the construction of a laboratory for the study of plague and the preparation of anti-plague serum which is probably unique of its kind. The building is situated within the fortress of Cronstadt, and is surrounded by water on all sides so that it is completely isolated. It is provided with stabling for twelve horses, and apartments for the staff and the assistants; there is even an isolation ward for the reception of any of the employés who may be unfortunate enough to contract the disease. It is self-lighted by electricity and communication with the mainland is secured by a small steam launch. No doubt the lamentable catastrophe at Vienna which startled the scientific world a few months since suggested these elaborate precautions. Such a laboratory is indeed as potentially dangerous in its way as a powder magazine, possibly even more so, because there still exists the theoretical risk of the conveyance of infection. It would, however, be difficult to suggest any further precaution short of condemning the staff to perpetual banishment on their island.

ANTONIO MACEO'S SKULL.

THE *Revista de Medicina y Cirugía* of Havana publishes an "anthropological study," by Dr. Montalvo, Dr. de la Torre and Dr. Montane, of the skull of the Cuban patriot, Antonio Maceo. The most noteworthy point is the existence of an interparietal, or, as it is sometimes termed, an "inca" bone, from the theory that it was universal amongst, and distinctive of, the old Peruvian race. This, however, was shown by Anoutchine to be erroneous, for after examining many thousands of skulls in various museums he found the bone in only 6.8 per cent. in Peruvians, in 1.5 per cent. in negroes, and in 1.3 per cent. in Americans. Maceo was, of course, of mixed race. The general character of the cranium approximates to that of the white race and indicates a man of remarkable capacity. The rest of the skeleton inclines more to the negro type and shows that he must have been a man of Herculean strength.

Correspondence.

A CENTENARIAN.

CLAREMONT, N. H., February 13, 1900.

MR. EDITOR: — I have been a subscriber to the *Boston Medical and Surgical Journal* for more than forty years. Recently I have seen reported several centenarians in the JOURNAL. I send you another centenarian and you can do what you think best with it.

Nathaniel B. Cross, born in New Salem, N. H., February 13, 1800. He is one hundred years of age to-day; eyesight sufficiently good to enable him to walk several miles about the streets daily; step very elastic; very erect; weight, one hundred and thirty-five pounds; has not taken liquor nor used tobacco for fifty years; he has no organic diseases; intellect clear; hearing excellent; sings; no tremor in voice. Mr. Cross resides in Claremont, N. H., with his daughter, Mrs. Babcock.

Yours truly,
A. R. CUMMINGS, M.D.

METEOROLOGICAL RECORD

For the week ending February 10th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

Deaths reported 2,649; under five years of age 887; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping-cough, erysipelas, fevers and consumption) 582, acute lung diseases 552, consumption 279, diphtheria and croup 103, measles 49, diarrheal diseases 32, scarlet fever 32, typhoid fever 28, whooping-cough 24, erysipelas 23, cerebrospinal meningitis 11.

From scarlet fever New York 23, Boston 8, Pittsburg and Springfield 1 each. From typhoid fever New York and Pittsburg 10 each, Boston 3, Malden and Washington 2 each, Baltimore 1. From whooping-cough New York 17, Boston, Pittsburg and Providence 2 each, Baltimore 1. From erysipelas New York

12, Boston 2, Baltimore, Somerville, Lawrence and Taunton 1 each. From cerebrospinal meningitis New York 5, Boston, Baltimore, Worcester, Gloucester, Newton and Medford 1 each.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,206, for the week ending February 3d, the death-rate was 21.2. Deaths reported 4,719: acute diseases of the respiratory organs (London) 432, whooping-cough 121, diphtheria 110, measles 83, diarrhea 40, fever 38, scarlet fever 33, small-pox (Hull) 2.

The death-rates ranged from 12.6 in Derby to 35.4 in Sunderland: Birmingham 25.0, Bradford 19.5, Cardiff 15.6, Gateshead 19.1, Hull 25.8, Leeds 23.1, Liverpool 28.5, London 19.6, Manchester 25.7, Newcastle-on-Tyne 22.0, Nottingham 18.3, Portsmouth 16.6, Salford 26.2, Swansea 15.3, West Ham 14.4, Wolverhampton 31.4.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 17, 1900.

M. H. SIMONS, medical inspector, commissioned medical inspector from September 24, 1899.

H. WELLS, medical inspector, commissioned medical inspector from January 15, 1900.

M. H. SIMONS, medical inspector, detached from the Naval Recruiting Rendezvous, New Orleans, La., and ordered to the "Philadelphia" as fleet surgeon.

T. H. STREETS, medical inspector, detached from the "Philadelphia" as fleet surgeon, on reporting of relief, and ordered to the New York Navy Yard.

J. C. ROSENBLEUTH, passed assistant surgeon, ordered to the Naval Recruiting Rendezvous, New Orleans, La.

H. N. T. HARRIS, surgeon, commissioned surgeon from October 21, 1899.

KARL OHENSORG, assistant surgeon, appointed from January 27, 1900.

G. L. BARBER, passed assistant surgeon, ordered to the "Kearsarge," February 20, 1900.

D. G. BERRE, assistant surgeon, detached from the "Petrel" and ordered to Port Isabella.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING FEBRUARY 15, 1900.

CARTER, H. R., surgeon. Upon expiration of leave of absence to report at Washington, D. C., for special temporary duty. February 13, 1900.

GLENNAN, A. H., surgeon. To proceed to Mobile, Ala., as inspector of unserviceable property. February 9, 1900. To proceed to Searcy, Ark., for special temporary duty. February 15, 1900.

MCINTOSH, W. P., surgeon. To proceed to Pensacola, Fla., for special temporary duty. February 9, 1900.

ROSENAU, M. J., passed assistant surgeon. To proceed to Philadelphia, Pa., for special temporary duty. February 9, 1900.

CUMMING, H. S., passed assistant surgeon. Granted leave of absence for fourteen days from February 21st. February 9, 1900.

TABB, S. B., assistant surgeon. Granted extension of leave of absence for fourteen days on account of sickness. February 14, 1900.

BURFORD, HUGH, acting assistant surgeon. Granted leave of absence for two weeks from February 15th. February 10, 1900.

KEYES, J. M., acting assistant surgeon. Granted leave of absence for sixty days from January 15th. February 10, 1900.

MONCURE, J. A., acting assistant surgeon. Relieved from duty at Gulf Quarantine and directed to proceed to South Atlantic Quarantine Station for duty and assignment to quarters. February 15, 1900.

SOCIETY NOTICES.

SUFFOLK DISTRICT MEDICAL SOCIETY.—The Section for Obstetrics and Diseases of Women will meet at 19 Boylston Place, Wednesday, February 28, 1900, at 8 P. M.

Papers: Dr. C. G. Cumston, "The Pathology and Symptomatology of Acute Pelvic Suppuration in Women and Treatment by Vaginal Colpotomy."

Dr. E. H Stevens, of Cambridge: "Parturition Complicated with Suppurating Fibroids."

Dr. E. S. Boland: "Immediate Repair of Perineal Tears."

R. A. KINGMAN, M.D., *Chairman.*
C. H. HARE, M.D., *Secretary,*
285 Marlborough Street.

INTERNATIONAL CONGRESS OF MEDICAL ELECTROLOGY AND RADIOLOGY. — At the request of the French Society of Electrotherapy and Radiology, the International Congress of Medical Electrology and Radiology, the initiative of which it has taken, is connected to the International Congress of 1900. This Congress will take place in Paris from the 27th of July to the 1st of August, 1900. All inquiries for further information must be forwarded to Prof. E. Doumer, General Secretary, 57 Rue Nicolas-Leblanc, Lille. Adhesions are to be sent to Dr. Moutier, 11 Rue de Miromesnil, Paris.

PROF. E. DOUMER, *General Secretary.*

UNIVERSITY OF PENNSYLVANIA MEDICAL CLASS OF '75.

The Executive Committee of the Society of Alumni has appointed the undersigned to endeavor to secure a reunion of the Class of '75 at the coming Commencement in June. Members of the Medical Class of 1875 who may see this are requested to send at once to me their present addresses and some brief account of their doings since graduation As many as possible of the class are urged to be prepared to come to a social gathering to celebrate its twenty-fifth anniversary.

CHARLES W. DULLES, 4101 Walnut St., Philadelphia.

RECENT DEATHS.

WILLIAM HENRY HOWE HASTINGS, M.D., M.M.S.S., died in Boston, February 16, 1900.

WOOLSEY HOPKINS, M.D., of New York, one of the assistant surgeons of the aural department of the Manhattan Eye and Ear Hospital, died on February 14th, of pneumonia. He was a graduate of the College of Physicians and Surgeons, New York, and thirty-five years of age.

EDWARD LORENZO HOLMES, M.D., former president of Rush Medical College, Chicago, died in Chicago, February 11th. He was born January 28, 1828, at Dedham, Mass., was educated at Harvard College and the Harvard Medical School, and was thereafter an interne at the Massachusetts General Hospital. His main work later in life was with the specialties of eye and ear.

BOOKS AND PAMPHLETS RECEIVED.

Mountain Fever. By E. Stuver, M.D., Fort Collins, Col. Reprint. 1899.

Ueber Ichthyolvasogen bei Gelenkaffectionen. Von Prof. Dr. G. Edlefsen in Hamburg.

Annual Reports of the President and the Treasurer of Harvard College, 1898-99. Cambridge. 1900.

The Phonographic Record of Clinical Teaching and Medical Science, Vol. VI, No. 2, February, 1900.

The Minor Surgery of the Nose and Throat. By George L. Richards, M.D., Fall River, Mass. Reprint. 1899.

VIVISECTION IN HARVARD MEDICAL SCHOOL.— A REPLY.

BY JAMES J. PUTNAM, M.D., BOSTON,
Professor of Diseases of the Nervous System, Harvard University.

It is well known that a bill to restrict experimentation on living animals was brought before the Massachusetts Legislature several years ago and was rejected after a number of full and impartial hearings, in which the attempt was vainly made to show that abuses existed in the work of our higher educational institutions. This year the same effort is being renewed, and should be opposed, not only by professional investigators but also by physicians and laymen who are conscious of the debt that the community owes to those who labor in the important fields of physiology and experimental pathology.

One of the most liberal of the supporters of the previous movement, Dr. Leffingwell, has recently distributed again, in pamphlet form, under the caption "Does Science Need Secrecy?"[1] a letter originally published in the *Boston Transcript* of September 28, 1895, as a reply to one by Professor Porter, of the Harvard Medical School, which had appeared two days before, and in it he makes a number of statements which should not be allowed to pass without notice, the more so because the fact is ignored that some of them had already been publicly shown to be erroneous. It seems to be as inevitable as it is unfortunate that the discussion should become public, — unfortunate, because so many persons in the community have shown themselves, again and again, ignorant of the value of the ends which are sought, and therefore unable to recognize how amply they justify the means that are used to gain them.

My objection to Dr. Leffingwell's pamphlet is not that it is critical but that it is unjust. It is an attempt to make it appear that men intentionally deceive who do not intentionally deceive; that men are cruel who are not cruel; that systems are in vogue which are not in vogue; that suffering is inflicted which is not inflicted; that the practical results of physiological research are of trivial value, whereas without them the splendid edifice of medical science could never have been built. The "practical" physicians who are so proud of the fact that they have exchanged the ignorant and brutal empiricism of the past for treatment based on a relatively accurate knowledge of the body in disease and health owe that knowledge, to an extent they often fail to realize, to the discoveries of these men, which have been incorporated like the "water of crystallization" into the working forces of the medical art.

It must not be forgotten by those who hold that it is wholly wrong to seek knowledge through experimentation on living animals (though we may make them suffer pain for our protection, our sport, our convenience, and our food), that Dr. Leffingwell is himself an avowed supporter of such experiments.

He says[2] "As a physician, I have never been able to go to the extreme of denouncing all experimentation upon animals whatever, even though from first to last no pain be felt. Between the total abolition of all sacrifice of animal life for scientific purposes demanded by many humanitarians and that absolute freedom to inflict torture without restraint claimed by some physiologists, there must be a middle ground." In another place he says,[3] "I am not an antivivisectionist, for I believe in the practice, when it is rigidly guarded against all abuses, limited to useful ends, and subject to public criticism and the supervision of the law."

No physiologist, so far as I know, claims freedom to "inflict torture" either with or without restraint: so that the main difference between Dr. Leffingwell's position and that of his colleagues with whom he disagrees is that he thinks the best safeguards against abuse, and the best way of limiting experimentation to "useful ends," to be "public criticism and the supervision of the law," while we trust far more in the character, traditions and training of the men who have this serious and important work in charge. If Dr. Leffingwell were only carrying out, as a practical physiologist, the carefully guarded experiments which he sanctions, he would be more ready to see the value of this latter guarantee, and less ready to endorse by implication the accusations of cruelty which he knows his pamphlet will lead the thoughtless public to bring against these men, in spite of their honorable records. Do these recitals, which, to those who read them, paint a scene of horror, really help the untrained reader to form a fairer judgment?

> "Judge the people by their actions,
> Is a rule we often get;
> Judge the actions by the people,
> Is a nobler maxim yet."
> — JAMES FREEMAN CLARKE.

If there is any subject that public-spirited men should treat soberly and dispassionately at the present day it is surely this subject. For every one must admit that within the past fifty years there has been a vast and rapid change in sentiment throughout the civilized world with regard to the infliction of pain, and that now and then the new wave takes on the character of an inundation. The bare mention of "abuses" in prisons, in asylums, in schools, in army discipline, excites a rush of indignation based on vague pictures of the days, not so long distant, when prisoners and witnesses were put to torture, and knowledge was conveyed at the rod's end, and lunatics were chained and punished. For this reason it is easy for leaders of reform, if they are willing to use such methods, to change a noble and useful sentiment into an hysterical and undiscriminating passion. And this is what is done when in the reckless determination to enlist public sentiment it is made to appear that the methods used by the most humane American physiologists are no better than those used by the least humane European physiologists; or that the customs which marked the research of half a century ago are the customs of to-day; or when by any means an uninformed public is encouraged to believe that our medical schools are dens of iniquity. Those who write upon these subjects are bound to hold themselves responsible not only for the words they use, but for the sense, so far as they can foretell it, in which their words will be taken.

It is not easy to realize, until one looks at the matter closely, what a powerful and even unreasonable influence this feeling has become. Anglo-Saxon communities are peculiarly affected by it, and the public

[2] Leaflet, Does Vivisection Need Concealment?
[3] Reply to Dr. Porter, p. 21.

has therein a stronger guarantee against physiological cruelty than any law could secure. Most of us approve of taking the life of animals for food, but even this is permitted only with the tacit understanding that the details shall be kept from our shrinking sight and ears. This is a pardonable sort of cowardice, but other forms are less pardonable.

It must indeed be admitted that indifference to others' pain is to be found everywhere, even in every home. But it is daily becoming rarer, and there is no country in the world where it is so rare as in ours. Let no one suppose that the flood of modern compassionateness and sensitiveness to the suffering of man and animals has left untouched the students and teachers of physiology. Humane physiologists would be as glad as any one could be, no doubt, to see the abolition of cruelty and the abolition of pain. But they are in better position than most persons to realize that their labors tend to the abolition of pain, both of men and animals, by increasing our knowledge of the conditions which underlie health and disease.

For my own part, although not a physiologist, I have been for more than twenty-five years a frequent, and at times a constant, visitor at the Harvard physiological laboratory, and familiar with the men who have raised it to its present position of usefulness, and the contrast between the impressions which I have received and those suggested by Dr. Leffingwell's pamphlet is so striking that I feel bound to testify to the untruthfulness of the picture which the latter draws.

No one would assert that in a quarter of a century there have been no instances of thoughtlessness, or that nothing has been done which has given cause for regret. Yet no unprejudiced observer could see a year's work at the laboratory without being compelled to admit, after due study of the conditions, that he had seen no evidence of real abuses, excesses, cruelty, or even of any considerable suffering. More and more effort has been made to increase the comfort of the animals, and they are now cared for in commodious quarters, and are removed from influences, such as solitary confinement, which might excite vague impressions of danger. They live as comfortably as those kept in well-regulated menageries or circuses.

I know, also, from conversation with Professor Bowditch, that he has studiously avoided, for many years, the class of experiments referred to by Dr. Porter in his letter as being distinctively "painful, and yet needing to be done without anesthetics."

It is obvious that the best sources of information as to the amount of pain suffered by animals used for the purposes of experimentation are the hospitals where men and animals receive surgical treatment; for the operations done by the surgeon are closely parallel, so far as the infliction of pain is concerned, to those done by the physiologist. Any unprejudiced person who will visit such a hospital will find that signs of severe pain are rare, and that the animals suffer much less than men. I do not, of course, refer to the suffering from the diseases for which the operations are done, but only to that which the operations induce.

Operations on the internal organs usually cause but little pain, so that, for example, as I have learned by personal inquiry, no anesthetic is needed, from first to last, for the removal of the ovaries from the mare, or other large animals, unless temporarily, if the skin has to be cut. Horses' teeth are usually pulled without an anesthetic, and I am told by a prominent veterinary surgeon that although this operation takes a relatively long time and requires the use of great force, yet the horse is so little affected by it that he instantly afterwards begins to eat, as if nothing had happened. This is worth remembering in connection with incidents like that reported by Dr. Bowditch in his address.[4]

Where operations requiring an anesthetic are to be done upon horses, chloral is commonly chosen, instead of ether, because of the struggling which the latter induces, and it is found that when a large dose of chloral is given the animal may sleep quietly through the entire period.

The operations of surgery are closely parallel to those of physiology, but the surgeon has few or no critics because the community understands and sympathizes with his aims. It excites no denial when the statement is made that patients suffer but little after even severe operations. Let it be assumed, however, for argument's sake, that this sympathy did not exist, and let the reader consider whether a description like the following would aid or would hinder him in the formation of a just opinion. "Of what use is it that you, the self-interested surgeon, tell us that the struggles of your half-etherized patient at the first plunge of the knife, the turgid and purple face, the groans and cries, are not indications of pain? You cannot persuade us that after these terrible mutilations of the deeper organs and cavities of the body, in which blood flows in torrents; this tearing out of the sensitive nerves of the face; these deep sections and lacerations of the brain and spinal cord; this crushing and scraping of diseased bones; that after these prolonged abominations the patient wakes in comparative comfort and indifference. We will not believe that the surgical wards of a hospital are habitually the abodes of cheerfulness; that the brain and most of the internal organs are nearly devoid of sensitiveness; that patients who have had injuries of the head involving serious destruction of the delicate mechanism of the parts within, or complete destruction of the spinal cord, may lie wholly conscious yet practically without pain, and not needing any anesthetic." Yet these statements are true, and it is also true that the work of the surgeon is the analogue and the counterpart of the work of the physiologist, but with the difference that the surgeon deals with the most sensitive and highly organized animal known, while the physiologist deals with those far lower in the scale of capacity for pain.

Let us look a little more closely at some of the special reasons that made it seem to Dr. Leffingwell so necessary to bring these charges against our teachers and our college.

I. He says (page 10): "In the first place Professor Porter does not well when he denies (as he seems to do) that the practice of experimentation upon living animals has ever led to abuse."

Dr. Porter's letter contains no such denial. It would have been an idle and uncalled-for statement, and one such as no one would think of making, even for surgery. Dr. Porter's letter was written to defend the experimentation which he and the Harvard Medical School represent from the terrible abuse which had been poured upon it, and if any reader doubts whether he was not within the mark in speak-

[4] At the annual meeting of the Massachusetts Medical Society in 1896, Prof. H. P. Bowditch gave an address on The Advancement of Medicine by Research, which was printed in the Boston Medical and Surgical Journal for June 11 and 18, 1896, and can now be obtained, with appendix, in pamphlet form.

ing of the "long-drawn lists of atrocities that never existed," let him study the records of the hearings before our own Legislature; let him even read Dr. Leffingwell's own pamphlet, and see if he thinks the expression overdrawn.

II. In the next section grave distrust is expressed as to the truth of Dr. Porter's words (reiterated by Dr. Bowditch at the legislative hearings) as to the work at the Harvard laboratory being done "within open doors," and the counter statement is made that "no feudal castle of the Middle Ages was ever more rigidly guarded against the entrance of an enemy than physiological laboratories are secured against the admission of unwelcome visitors." As a matter of fact, the agents of the Society for Prevention of Cruelty to Animals have several times called and witnessed experiments, with Dr. Bowditch's full consent, and he authorizes me to say that any one who applies in a spirit of serious inquiry will be welcome in the future as in the past.

Possibly some reader of Dr. Bigelow's address of 1871, of which such liberal use is made, may think that through him they obtain a real look behind the closed doors of the Harvard laboratory, and for that reason I pause to call attention to the fact that when this address was delivered the Harvard laboratory did not exist, and that Dr. Bigelow's knowledge of vivisection was derived entirely from acquaintance with the French methods of half a century ago. To him, however, at least, the doors of our laboratory were surely never closed, and yet it is not known that either in private or public he ever made a protest against its establishment or its development, or uttered an unfavorable criticism of any act done within its walls. Moreover, this laboratory was established at a time when Dr. Bigelow was the most influential member of the Faculty, and it could hardly have been established without his consent. Thousands of students, since that day, have passed through the Medical School, with full power to know every detail of the work of the physiological laboratory, and no one of them has been found ready to endorse any charge of wanton cruelty, or the other statements contained in Dr. Bigelow's address.

III. In the name of scientific accuracy, Dr. Porter is taken to task for his statement that through the discovery of the tetanus antitoxin tetanus is taken out of the list of incurable diseases. Dr. Leffingwell points out that many patients with tetanus used to recover before this discovery was made, and that even in spite of it many now die. Both of these facts are too well known to have needed restatement by either writer, and Dr. Porter's remark, in the sense in which it was obviously written and in which any candid reader would understand it, is certainly correct. Before the use of tetanus antitoxin a great many patients with tetanus recovered, it is true, but the physician stood almost helpless. He could sometimes mitigate the symptoms a little by narcotics, and could help sustain the patient's strength, and that was all. But with the discovery of antitoxin the treatment of this terrible disease entered on a new phase. Henceforth, and for the first time, the disease could be met by a rational weapon, and the actual accomplishment, though far less, when Dr. Porter wrote, than it is now, seemed even then the earnest of a far greater accomplishment in the future. The "disease" had been shown not to be "incurable," and the demonstration was one to call for grateful rejoicing. Dr. Leffingwell's criticism appears all the more unwarrantable when it is remembered that Dr. Porter obviously referred to the antitoxin of tetanus only as one of various agents by which physicians, under the lead of the experimental physiologists and pathologists, are now able to make some head against contagious disease. He might equally well have chosen the diphtheria antitoxin for his example, and would then have had a more impressive array of statistics to drive his argument home. Virtually, however, the two cases are parallel. Many patients with diphtheria used to recover; some still die in spite of antitoxin; and there are not wanting authorities who could be cited as disbelieving in the new treatment, by any one that wished to minimize its importance. Yet there is now a great flood of testimony to its value, prominent among which is that from the contagious wards of our City Hospital.

Under IV and V, Dr. Leffingwell deals with the question of "anesthetics" and "narcotics," and denies the justice of the claim which Dr. Porter makes, that animals are kept from suffering any considerable[5] pain, by such means, when operated on at the Medical School. Here, again, the difficulty of securing from any large number of people the same consideration for the physiologists' view that is accorded freely to the arguments of its opponents is so great as to justify a special appeal to those who would be fair to let careful thought and study precede judgment. The argument is that ether and chloroform are the only true "anesthetics"; opium and chloral being "narcotics, which excite a degree of torpor, though they do not prevent pain"; while curare only paralyzes movement and does not affect sensibility at all.

These statements contain truth, yet not the whole truth, nor do they show that Dr. Porter's remarks, if taken in the sense in which they were obviously intended, are untrue.

Curare, to begin with, does, in large doses paralyze the sensory nerve-endings,[6] and is likely, even in smaller doses, to blunt their excitablity.

Apart from this, however, I have Dr. Bowditch's authority for saying that curare is rarely employed nowadays[7] at our laboratory, except in conjunction with other anesthetics, or where a non-painful experiment was to be done which would nevertheless be interfered with by accidental movements.

The object of giving the curare is obviously misunderstood by Dr. Leffingwell and those who write in his mood. The very mention of the word excites indignation, and it is generally believed that it would never be used but to prevent the struggles of an animal in pain. This sentiment finds expression, among other places, on page 4, where he discusses the statement originally made, I believe, by Ludwig, and cited by Mosso in the biography of his great teacher, to the effect that many experiments would be made impossible by the occurrence of pain.[8] Dr. Leffingwell rejoins that it is not the pain which interferes with the

[5] I insert the last two words as expressing more accurately what I believe to have been Dr. Porter's meaning, and as, at any rate, illustrating my own.

[6] See, for example, T. Lauder Brunton's Pharmacology, Therapeutics and Materia Medica.

[7] Mention was made in the earlier part of the paper of a class of experiments which are not now made.

[8] I do not quote the exact expressions used, partly because I have not had access to the original, but mainly because I am not undertaking to defend Mosso but simply trying to explain a physiological misunderstanding.

experiment, but the movements which the pain excites, and says: "What the Italian physiologist might truthfully have written was this: 'It is an error to believe that physiological experiments requiring the aid of delicate instruments can be performed upon an animal which is not made incapable of muscular effort.'"

This is not at all what either Ludwig or Mosso meant. It was not the movements, but the pain as such, reacting, as pain always does, on the delicate mechanisms of respiration and blood pressure, and the heart's action, which, if present, would have seriously interfered with the careful study of those important functions, and any one who chooses to look into the matter will find this to be the case. The occurrence of pain would have been fatal, likewise, to the success of some of Dr. Porter's experiments on the respiratory nerves, which Dr. Leffingwell criticises.

When curare is used after or during etherization, as in some of the experiments cited, it is because the painful parts of the operation are only at the beginning. For the later stages it is only necessary to use some means of preventing the movements which the animal would make involuntarily or spontaneously on coming out of ether, and which would render the desired observations impossible.

V. It is necessary to turn next to the consideration of the kindred and yet different question, namely, whether it is true that a fundamental difference exists between "anesthetics" (ether and chloroform) and "narcotics" (morphine and chloral), using the terms in Dr. Leffingwell's sense.

The best answer is that it is a matter of common knowledge that both morphine and chloral relieve pains of every sort, and they would unquestionably be "used by the surgeon" for operations, if ether and chloroform were not, for obvious reasons, better adapted to that special purpose.

Dr. Leffingwell insists, on the basis of his citations, that narcotized animals continue to feel. I wish it to be understood, however, that, even if this be true, to feel is not necessarily to suffer. A hypnotized person, to whom it has been successfully "suggested" that the pricking or cutting of his skin will not cause pain, may "feel" what is done to him but he does not "suffer." Similarly, when a person is even heavily poisoned by morphine, so that he is wholly indifferent to most excitations, an especially powerful stimulus will excite a momentary jerk or movement of resistance, quite sufficient to show that his muscles are not paralyzed and that his nerves still conduct impressions. On the other hand, his whole demeanor and his testimony after recovery prove that he was incapable of "suffering."

A few words must be said about the *dose* of chloral used by Dr. Porter. It is certainly the case that rabbits can bear a much larger dose than one-tenth gramme without death, but it must not be forgotten that this quantity would be equivalent to something like sixty or seventy-five grains for an adult man, assuming that a man weighs about forty or fifty times as much as a rabbit. This would be a huge dose, and although rabbits are undoubtedly relatively less sensitive than men to this drug, yet a grain and a half is not for them an insignificant quantity.

Under Section VI, Dr. Leffingwell cites a portion of the details of experiments by Drs. Ott, Walton, Hooper, Ellis, Bowditch and Porter, to controvert the statement which the latter made about "painless experiments." I stated, at the beginning of this paper, that experiments wholly without anesthetics, or only with curare,[9] are not now made at our laboratory, and have not been made for many years, and for this reason I omit the discussion of Dr. Ott's investigations, the more so that I have had no opportunity to talk with their author about them.

On pages 16 and 17, Dr. Leffingwell cites the details of an experiment by Dr. Bowditch upon nerves, to show its painful character, though a moment's further reading might have shown him that the nerve was in each case severed from the brain, so that the "stimulation" of it was no more felt by the animal than the stimulation of an amputated limb would be felt by the patient from whom it came. The "curare" in this case was given not to prevent the struggles of a victim in pain, but to eliminate involuntary or spontaneous movements such as any animal, in pain or not, might make, and to prevent the nerve stimulation from causing muscular contractions which would have interfered with the observations on the circulation of the blood.

In Dr. Porter's experiments, also, it was the *peripheral* end of the phrenic nerve which was "seized and torn out of the chest," and before this was done the nerve had been rendered insensitive and incapable of conducting impressions of any kind, even if it were not a fact that the phrenic nerve is a nerve of motion and probably conducts no sensations of pain at all. Dr. Leffingwell might easily have ascertained that the "struggling denoted by the stars," did not occur at the moments when the supposed-to-be painful excitations were made, but corresponded to movements not associated with the excitations at all. He might have found, what Dr. Porter assures me was the case, that in the experiment with regard to which it was not stated that anesthetics were used, they were used as in the other experiments. Any physiologist, any reader, indeed, not seeking merely to find a new point of attack, would draw this obvious inference, or would have written to ask Dr. Porter with regard to the facts.

By similar inquiries Dr. Leffingwell would have found that Dr. Walton's experiments[10] caused but little pain, as surgical experience proves, and that they were undertaken to show that the surgeon, in removing the epiglottis, which sometimes must be done, can save his patient from serious difficulty in swallowing if he takes pains to limit his incision within a certain anatomical line which Dr. Walton points out on the basis of his experiments. Had he investigated further he would not have shown such ungenerous readiness to describe in detail Dr. Bowditch's "clamp," and couple therewith the suggestion that its use indicated the falsity of the statement that anesthetics were habitually employed, since then, he thinks, it could not be needed, for he would have found that it was primarily used as the best means of furthering the production and maintenance of etherization, and, next, as a convenient method for holding in a given position the fully etherized animal.

I shall not follow Dr. Leffingwell into further discussion of the details of these experiments. It is unfitting to paint such pictures for a public untrained

[9] Except as explained above.

[10] This statement is authorized by Dr. Bowditch, who conducted the investigation with Dr. Walton.

to estimate either the pain suffered or the good accomplished. Those who wish can find them where they are given, with no attempt at concealment, in the physiological literature of the world. Indeed, if the word of men so respected as Dr. Bowditch and Dr. Porter is no longer to be believed, and parties must be formed among the public, representing the two sides of this discussion, it would be desirable that every one who means to form an opinion should read these descriptions carefully and for themselves, not in extracts as part of a revolting picture painted by an unfriendly critic. We appeal, however, to right-minded persons who undertake this task and who value their own opinions and do not wish their consciences laden with the reproach of having helped to check a movement which exists not to increase but to diminish the sum of suffering in the world, to withhold their judgments until they have truly studied the subject of animal pain on the one hand and the position of physiology as a means of promoting the happiness of men and animals on the other. They may profitably begin by reading carefully a book published in London in 1883, called "Physiological Cruelty," from which Dr. Bowditch quoted in his admirable address before the Massachusetts Medical Society in 1896.

I have studiously avoided, in this paper, attacking Dr. Leffingwell's motives in any way that he could consider unjust. I accuse him of nothing but the thoughtlessness of fanaticism and ignorance. But to this charge he certainly is open when he uses the following statement for the sake of making it appear that the late Dr. F. H. Hooper was inhumane in his experimental work: "If one desires to see the picture of a dog 'thoroughly etherized or chloralized,' fastened immovably, its throat cut, and its larynx dissected out and tied up with a string — an experiment from the physiological laboratory of Harvard Medical School — let him consult one of Dr. Hooper's papers."

It is easy to imagine that this picture should excite such a feeling of horror among the ignorant as to deprive them of the power of judgment, but how it serves the interests of truth and fairness is not clear.

Is it possible that Dr. Leffingwell does not know that these animals, being under the effects of ether, felt these manipulations hardly more than a block of stone? Is it possible he does not know that practically the same operation, the removal of the larynx, and others far more likely to be painful, are done by the surgeon and without causing pain? What did he expect to be the effect of the remark that the larynx was "tied up with a string"? It was absolutely necessary for the experiment, and it certainly did not hurt the animal, but the reference to it as certainly did excite a feeling of unreasoning indignation against Dr. Hooper, such as it might have been thought that Dr. Leffingwell would have been glad to see eliminated from this discussion.

It may surprise those whose only acquaintance with Dr. Hooper has been through this reference to hear that he was a man of extremely kindly instincts and exceedingly fond of the animals most used for these experiments, one or more of them being his almost constant companions.[11] His keen interest in laryngology, fostered and guided by his physiological studies, had made him a leader in clinical work of the most practical kind. The day will surely come when the painful disease of which he died will yield its secrets to the researches of the pathologists and the biologists. May America not be behindhand in contributing to this great work!

It is difficult to believe that any thoughtful and liberal-minded person can suppose physiology to be able to thrive without the opportunity of verifying hypotheses by experimentation on living animals; or practical medicine to be able to thrive without physiology. It is only by painful and laborious effort that medicine can succeed in reclaiming for health the vast domain of disease, and no auxiliary can be spared that might make this conquest swifter or surer.

We do not want to see our medical schools reduced to third-rate institutions because unable either to teach adequately the first elements of medical knowledge, or to secure the only teachers who are worth having, the teachers who are likewise investigators. We do not want to see American research strangled or given over to inferior men, nor do we wish to see restrictions imposed which annoy without materially restricting.

Those of us who have been interested in noting what physiology has done for practical medicine, and in attempting to gauge fairly the amount of the pain to animals which this sort of research involves, believe that we can see the difficulties which laymen find in forming opinions, and can appreciate and admire the humane feelings which prejudice them against the physiologists. But we believe that they are laboring under serious misconceptions as regards the facts at stake. It is easy for them to understand the arguments of those who think that experimentation upon animals is wrong and painful; it is difficult for them, if they have not specially studied the subject, to appreciate the arguments for the other side. Every one is ready to assume, as a safe principle, and in the interests of humanity, that a manipulation which causes pain to a man causes the same pain to an animal, forgetting or overlooking the fact that the best criteria of real suffering are exhaustion, prostration of nerve force, incapacity for immediate exhibition of the usual appetite, the usual power of enjoyment, the usual interest in familiar occupations, and that, judged by these standards, vast numbers of acts from which men would suffer cause but little inconvenience to animals lower in the scale.

So, again, when the value of such experimentation is under discussion, it is easy for the untrained to appreciate the arguments of those who say that little or no good comes of it all, and practically impossible for them to recognize what is accomplished, unless they are willing to devote themselves with unbiased minds to a careful investigation of the question. And this they should feel bound to do before they lend their names and influence to help cripple a means of study which multitudes of men whom they must respect tell them has been of vast service to mankind.

The demand is often and naturally made that definite results of practical value should be pointed out as immediately flowing from each given series of experiments, and when it is replied that this is not always possible, the motive of "curiosity" is liberally suggested. But let any fair-minded person go to the laboratories of chemistry, or of physics, or to the as-

[11] Ludwig, also, who was Dr. Bowditch's teacher, and whom I had the privilege of knowing, not only won by his character and kindness the affectionate devotion of a host of friends and pupils, but earned the gratitude of his townspeople for many acts of public spirit, among which was the instituting of reforms in the treatment of horses.

tronomical observatories, and transfer his demand there, and he will perceive how irrational it was to have made it at all. How often does a single series of experiments in those departments lead to a brilliant discovery? Yet how few great discoveries would ever have been made but for the silent and patient investigations into minor problems that to the untrained observer often seem trivial and irrelevant. Let the motive be called "curiosity" if one chooses, but with distinct recognition of the fact that the "curiosity" of the man whose mind is filled with knowledge, and whose instincts are keen to divine the part that his work will play in the final structure, is one of the greatest forces of progress.

Many of these investigations, in every department, seem to turn out blind alleys, and to end for the moment in nothing. It is inevitable that this should be so, until men have infinitely greater powers than now wherewith to fathom the vast unknown. But discovery comes by study and only so, and many a failure, conscientiously interpreted, proves to be the fingerpost to an important truth. The splendid generalizations, like that with regard to the germ theory of disease, through which the practice of surgery and medicine has been revolutionized, are, to the lay mind, the most obvious triumphs of experimental research. But he who seeks out the sources from which practical medicine really derives its strength will be amazed to find that there are many other achievements just as important as these, though of a different order.

The difficulties in the way of medical progress are so great that practical physicians are under a constant temptation to cease trying to surmount them, and to let themselves degenerate into routine practitioners, or pure empiricists. Even the great geniuses would more often lead us astray, as they have repeatedly done in the past, were it not that the experimentalist is ever at hand to apply the touchstone of criticism or hold up the torch of inspiration and guidance. If the expression "A power behind the throne" was ever justified, it is justified as expressing the relation of experimental physiology and pathology to practical medicine.

It is obviously important that all this experimentation should be conducted according to the most humane sentiments of our day, but also in such a manner that each observation shall yield its due share of benefit, and not be wasted. Surely the best means of securing the observance of these conditions is to support our institutions of learning so that they can secure teachers and investigators with wisdom to desire the highest knowledge, and powers trained to find the surest path to reach it, and characters which would make them incapable of inhumanity. Many a person who is now trying to invent some ingenious method for hampering and hedging the work of the physiologist would recall with a feeling of shame how much suffering and calamity was brought upon this country during our Civil War by the attempts to rule the generals from Washington, and by the foolish clamor of those who wished the struggle abandoned because their narrow vision only let them see the present distress that it entailed. The war against disease is like any other war, and can only be carried on successfully with trained generals, supported by public opinion, and allowed to choose their own methods.

Is it legitimate to use experimentation upon living animals for the purposes of teaching as well as for the purposes of research?[12] There are many persons who would answer this question in the negative. But let it be remembered, on the one hand, that the students of to-day are the teachers and investigators of to-morrow; and, on the other hand, that even as fitting themselves to be physicians, the knowledge that they derive from actually seeing an experiment is of a wholly different order from that which they derive from hearing about it. Here, also, it is a question of how to make experimentation bear its fullest fruit. It should, of course, be remembered that, so far as warm-blooded animals are concerned, they are always in a state of anesthesia, and incapable of suffering considerable pain when the demonstrations are being made.

The study of medicine and physiology is no child's play. It is a serious business, and a good medical school should see to it that the men whom they graduate realize to the full the responsibilities and problems with which they are to come in contact. If they do this better for having had an important truth driven home by an ocular demonstration upon a narcotized animal, then the demonstration was worth making. The charge that students become hardened to suffering in this way is as baseless as the similar charge occasionally brought against surgeons.

It has not seemed possible, or desirable, to attempt in this paper to enter exhaustively into all the questions that suggest themselves to the mind in connection with this controversy; my main object has been to bear witness to what I have seen. I should like, however, to state that in my opinion the position of those who strive for "total prohibition" is hardly more unreasonable than that of those who, like Dr. Leffingwell, have temporarily joined hands with the total prohibitionists, but really wish only to see annoying restrictions imposed upon men hitherto trusted in all things.

The injustice of legislation like that now in force in England, which admits that experimentation on living animals is justifiable, but attempts to substitute for the conscience and knowledge of the trained investigator the judgment of men no better or wiser than himself and infinitely less well equipped for estimating the probable value of his work, recalls the prolonged attempt to establish a censorship of printing, against which Milton wrote, in 1644, his eloquent protest, "Areopagitica; Defense of the Liberty of Unlicensed Printing." I recommend to every lover of liberty and progress the reading of his manly and invigorating plea.

CHRISTIAN SCIENCE IN MARYLAND. — A bill is now before the State Legislature of Maryland restricting the practice of medicine to duly qualified physicians, and providing that "any person shall be regarded as practising medicine within the meaning of this act who shall attempt to heal, operate on, or prescribe for any ailment of another." A public hearing held last week brought out a large number of Christian Science remonstrants. The wording of the bill is perhaps rather too comprehensive, though it will no doubt tend to suppress the practice of Christian Science.

---

[12] I do not refer, of course, in what follows, to the question of demonstrations in high and grammar schools, which have already, and very properly, been forbidden by law.

STRICTURE OF THE URETER A POSSIBLE RESULT OF LACERATION OF THE CERVIX UTERI, AND URETEROVAGINAL FISTULA A RESULT OF TRACHELORRHAPHY.[1]

BY E. C. DUDLEY, M.D., CHICAGO, ILL.

For purposes of illustration I offer the following history of a case. All details not belonging to the subjects under discussion are purposely omitted. The patient was thirty-seven years of age and married. The oldest child was twenty-one and the youngest one and a half years of age. Date of first consultation was March 29, 1899.

Subjective symptoms. — In addition to the usual symptoms of menorrhagia, mucopurulent uterine secretions, dysmenorrhea, vesical irritation, headache and nervousness, the patient, since the birth of the first child, twenty-one years before, had suffered from pain referred to the left inguinal region; this pain was of variable intensity, always annoying, often quite severe, and was the chief and significant subjective symptom.

Examination. — Examination of the pelvic organs, in so far as it relates to this discussion, gave the following results: Uterus symmetrically enlarged from endometritis and metritis, the canal measuring three and a half inches in length. Position of uterus normal. Bilateral laceration, great circular enlargement, cystic degeneration, erosion and eversion of the cervix uteri. The cervical laceration on the left side was extreme; it had extended far into the vaginal wall and parametria and had healed by much cicatrization. The perineum was lacerated to the sphincter ani muscle. Uterine appendages normal.

Operative treatment. — April 20, 1899. The cervix uteri and perineum were closed. The operation on the cervix was that of Emmet, as modified by Schroeder, and involved the resection of considerable tissue from the thickened lips. The denuded surfaces at numerous points were quite hemorrhagic, so that both in the cervix and perineum some difficulty was experienced in the control of hemorrhage.

Nine days after the operation there suddenly appeared dangerous hemorrhage from the vagina, and my interne, unable to find me, called one of my colleagues, who promptly etherized the patient, and by the introduction of sutures under the bleeding points, close to the uterus, arrested the hemorrhage, and, as I think, saved the patient's life. Two days later urine began to pass voluntarily through the vagina. Further observation, however, showed that a part of it also passed normally and voluntarily through the urethra. This lead to the suspicion that one of the ureters was probably discharging urine directly into the vagina and the other into the bladder. Examination of the vagina by means of Sims's speculum showed at the line of union to the left of the cervix where the laceration had been most extensive an occasional spurt of the urine. The attempt, however, to pass a ureteral bougie from this point failed. Dr. Kolischer, who has great skill in electrocystoscopy, kindly saw the patient with me at this time. He distended the bladder with water and by means of a Casper cystoscope readily passed a bougie into the right ureter. The left ureter, however, was occluded, so that the smallest bougie would only pass about five-eighths of an inch inside the ureteral orifice. The diagnosis was now established of a ureterovaginal fistula of traumatic origin on the left side and of obliteration of that part of the ureter situated below the fistula. It was evident that one of the sutures or ligatures, either at the time of the original operation or at the time of the hemorrhage, had been passed around this ureter and had slowly cut it off or had so transfixed the ureteral wall as to open it. One week after the hemorrhage the sutures were removed. During the following four weeks the nurse reported that the discharge of urine through the vagina was not constant. Urine apparently accumulated in the ureter and pelvis of the kidneys and was discharged at intervals. Upon speculum examination about three weeks after the hemorrhage, the injured part of the vagina being exposed for thirty minutes, no urine was seen to escape. The patient, however, reported that urine had sometimes been retained for three or four hours and had then escaped in considerable quantities through the vagina.

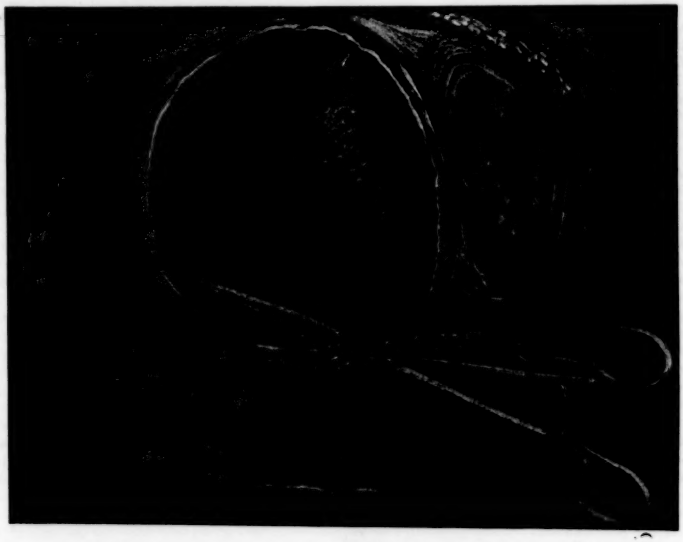
On the 2d of June, thirty-five days after the hemorrhage, with the purpose of performing some operation to re-establish a free communication between the injured ureter and the bladder, I again etherized the patient. For more than three-quarters of an hour with uterine tenacula and a fine probe I sought in vain for the point where the ureter opened into the vagina. No urine came through to mark this point, and even after some rather extensive dissection with the scissors I was unable to locate the fistula, nor was I able to make out the ureter by palpation. Finally, however, a little spurt of urine appeared just to the left of the cervix uteri, but I was unable at this point to pass even a very fine probe. Each attempt only resulted in the making of a false passage — a thing difficult to avoid under such conditions. I then made a colpocystotomy, cutting with the scissors through the vesicovaginal wall in the median line and in the long axis of the vagina just in front of the cervix. The vesicovaginal fistula thus made was an inch long. The upper extremity of it terminated close to the anterior wall of the cervix uteri. With a pair of straight scissors I then extended the incision upward and to the left as nearly as could be estimated to the point whence the urine had escaped. The object was if possible to convert the ureterovaginal fistula into a ureterovesicovaginal fistula; so that the ureter should open, not into the vagina, but into the margin of a vesicovaginal fistula. After another long search I again failed to find the fistulous opening into the ureter, until it was located by another spurt of urine, but the opening was too small to admit even a very fine probe and therefore could not be entered. I then still further enlarged the vesicovaginal fistula in a direction to the left of the uterus, and by good fortune opened into a very much dilated ureter, from which immediately there gushed two or three ounces of pent-up urine. The dilatation explains the fact that I had been unable to locate this ureter by palpation. A bougie passed without obstruction to the kidney thereby proved the absence of any constriction above.

The situation being now much simplified the following procedures were adopted: The bladder mucosa was stitched to the vaginal mucosa all around the artificial vesicovaginal fistula. In this way the exposed surfaces were covered and hemorrhage controlled. A hemostatic forceps, with handles about four inches

[1] Read by invitation before the Boston Obstetrical Society, December 19, 1899.

long and with slender jaws about an inch long, was passed into the vagina and through the fistula. The forcep jaws were then passed, one into the ureter and the other into the bladder, so that the forceps when locked included in their bite, ureteral wall, bladder wall and the connective tissue between. In this way the lower extremity of the cut-off ureter was clamped into close relations with the bladder. The expectation was that the structures within the bite of the forceps would be destroyed by pressure necrosis, and that a wide free ureterovesical opening would be established at a point somewhat distant from the artificial opening into the bladder, and that in this way the case would become one of uncomplicated vesicovaginal fistula. The forceps came off in about three days, and twelve days later the vesicovaginal fistula was closed by suture in the ordinary way. At the time of this operation the new ureteral orifice was found to be perfectly open and very patulous. The subsequent history was uncomplicated, union was complete and in a short time the patient was discharged cured. In a letter written about six months after the final operation the patient reported entire freedom from the pain in the left inguinal region from which she had suffered, and which had made her a semi-invalid for twenty years. I regret that the ureter was not explored before the operation, and that it has not been practicable to obtain measurements of it since.

My experience in the surgical treatment of ureterovaginal fistula is limited to only two other cases, one traumatic and one congenital. In these two cases I operated at St. Luke's Hospital, Chicago, seven or eight years ago. The operative treatment in each was like that just described, except the ureteral and vesical walls were divided by scissors instead of being clamped by pressure forceps. In these cases, however, the ureteral openings were much nearer to the trigone, and the lower extremity of the injured ureter therefore was quite close to the bladder mucosa. In the case just reported the distance and amount of tissue between the bladder and ureter was so great that it could hardly have been divided with the scissors without danger of uncontrollable hemorrhage or of the exposure of broad surfaces to reunite, or to cicatrize and contract, or to suppurate. These difficulties were obviated by clamping the ureter into close contact with the bladder so that when the forceps came off, the exposed surfaces left by the necrosis would, owing to the compression, be of small extent. The compression forceps used in this way, therefore, may make the operation practicable in those regions where the tissue between the ureter and the bladder is too abundant to be safely divided by scissors. Howard Kelly, in his recent book, describes an operation of switching the ureter into the bladder through an artificial vesicovaginal fistula. I have proposed the operation just described in the hope that it will give the greatest security against subsequent stricture at the new ureteral orifice.



Traumatic ureterovaginal fistula as a result of trachelorrhaphy is rare, but as a result of vaginal hysterrhaphy and other vaginal sections is not of infrequent occurrence. The operation above described is applicable to the condition, whatever the cause, whether traumatic or congenital. The alternatives to the operation are well known and need not be described. To open the abdomen, sever the ureter and insert it into the bladder wall is an operation of great difficulty and danger and sometimes of only transient value. The same may be said of dissecting or stripping the bladder from the pelvic wall, finding the

ureter and inserting it into the bladder without invading the peritoneal cavity. The utilization of vaginal mucosa in a plastic operation for the purpose of diverting the urine from the vagina to the bladder usually results in failure of union, or, later, in cicatricial contraction and consequent stricture at the ureteral orifice. Switching the ureter into the intestine or into the opposite ureter are both questionable procedures.

As a corollary to the case just described I now bring before you an observation that, if well founded, may prove to have some practical significance. It is probable in this case that the laceration having extended into the parametria had torn the structures around the ureter. There may also have been injurious pressure of the presenting part of the child against the ureter. Such lacerated tissues would necessarily heal by cicatrization and contraction, and the cicatrix thus formed would draw the bruised ureter towards the uterus, compress it and so give rise to obstruction both from stricture and from kinking. This mechanism will account for the facts of the case. The contracting cicatricial tissue extending from the cervix uteri around the ureter would necessarily draw the ureter into closer proximity to the uterus, where a deep suture applied for closure of the cervix or to control bleeding would be apt to injure it and by compression would cause a narrowing of the lumen of that part lying within its grasp. In this case the stricture extended at least a half-inch on either side of the ureteral fistula. It was evidently this constricted portion of the ureter that was caught by the needle and cut off or penetrated by the suture.

It would be quite impossible, without further observation, to estimate the proportion of cases in which laceration of the cervix uteri causes stricture or kinking of the ureter. In this connection, however, every gynecologist may revert to a class of cases not small, in which there is extensive laceration of the cervix uteri on one or both sides, usually on the left, and in which the localized pain on the corresponding side of the pelvis is not readily accounted for by palpable lesions, such as disease of the uterine appendages or of the appendix vermiformis. The continued pain in such cases dates from the puerperium, is always out of proportion to the palpable pelvic lesions and is not relieved in the slightest degree by the repair of the cervix. As I look back over an experience of more than twenty years I recall many such cases; the one just reported apparently belongs to this class.

But why, one may ask, if the ureter is often drawn by cicatricial contraction close to the uterus, is it not more frequently injured by operations on the cervix? The answer is that if the sutures of trachelorraphy were not usually introduced close to the uterus or very superficially in the vaginal wall more cases of ureterovaginal fistula would probably be reported. This case was very hemorrhagic and therefore required exceptionally deep sutures to control the bleeding. In view of the facts already set forth I desire to submit two questions, as follows:

Question I: In all cases of extensive laceration of the cervix uteri, in which the localized pain is not accounted for by palpable lesions, should we not pass a series of graduated ureteral bougies on the side corresponding to the laceration? This would be for the purpose of measuring the calibre of the ureter and of locating a possible stricture. The principles of examination would be similar to those of measuring the calibre of the male urethra in the diagnosis of stricture.

Question II: In a case of ureteral stricture due to laceration of the cervix uteri, or to any other cause, and situated within the range of a vaginal operation, would not one be warranted in opening the bladder and then proceeding, as in the case reported, to establish a new ureteral orifice? In other words, should not that condition which in this case was the result of an accident be deliberately reproduced in similar cases?

My own answer to these questions would be in the affirmative.

THE RELATIVE HUMIDITY OF OUR HOUSES IN WINTER.

BY ROBERT DE C. WARD, CAMBRIDGE, MASS.,
Instructor in Climatology in Harvard University.

In discussing with my classes in climatology the various ways in which climatic conditions affect man, I have been accustomed to point out that the climate which we have been able to produce inside of our modern houses is an extremely artificial one. We shut out the winds, and live in an atmosphere which is prevailingly calm. We keep out rain, snow, sleet and hail, and thus spend most of our time where there is no precipitation of any sort. In summer we are able to keep the air in our houses cooler than that outside by closing windows and blinds, and by means of artificial ventilation. In winter our houses are heated, and we live in an atmosphere which is many degrees warmer, and very much drier, than that out of doors. This dryness of the air indoors in winter I have been in the habit of comparing with that of deserts, although I have never used any numerical data in making this comparison. In view of the importance of this matter from a physiological point of view, and also because of my desire to present my students with humidity data obtained by actual observation indoors, I have recently made a short series of simple observations along these lines, which may have some interest for the readers of the Journal.

These observations were made in my study by means of one of H. J. Green's ordinary sling psychrometers. The room in question is heated by hot air, from an ordinary hot-air furnace, provided with the usual small — ridiculously small — evaporating pan. Inside the register there is a vessel holding a little more than half a litre of water. This pan has to be filled about once a day, although the rapidity of evaporation depends so directly upon the amount of heat from the furnace that the time needed to evaporate the water varies considerably. Observations were made during three weeks of last November (November 3d–23d), from two to five times daily, as opportunity offered. The hours of observation necessarily varied. Each record included the readings of wet and dry bulb thermometers, and a note as to the condition of the weather outside; the amount of ventilation by means of the windows; the degree of heat coming from the furnace, and the amount of water in the evaporating pan inside the register.

A summary of the mean daily temperatures and relative humidities indoors and outdoors is given in the following table. In the case of the data for the outside air the readings were taken from the sheets of the Richard thermograph and hygrograph at the Har-

vard College Observatory, the hours to which the individual readings correspond being the same as those at which the observations were made indoors. These means for the outside air are therefore not the true means for the day, but they serve for the purposes of the present comparison:

Date.	No. of Observations.	Inside Air.		Outside Air.	
		Mean Temperature.	Mean Relative Humidity.	Mean Temperature.	Mean Relative Humidity.
November 3.	5	69°	28 per cent.	75°	66 per cent.
" 4.	5	71°	30 "	42°	69 "
" 5.	5	71°	30 "	43°	64 "
" 6.	4	69°	29 "	34°	68 "
" 7.	5	68°	32 "	39°	63 "
" 8.	5	71°	31 "	44°	69 "
" 9.	4	69°	32 "	42°	69 "
" 10.	3	67°	34 "	47°	60 "
" 11.	4	69°	33 "	38°	77 "
" 12.	3	64°	30 "	29°	70 "
" 13.	4	67°	24 "	23°	51 "
" 14.	3	67°	26 "	25°	75 "
" 15.	3	71°	31 "	28°	91 "
" 16.	4	72°	29 "	36°	68 "
" 17.	2	68°	27 "	24°	66 "
" 18.	2	64°	31 "	28°	90 "
" 19.	3	71°	40 "	42°	87 "
" 20.	3	70°	28 "	39°	69 "
" 21.	4	69°	25 "	41°	70 "
" 22.	4	71°	30 "	46°	71 "
" 23.	3	72°	26 "	43°	72 "
Means.		69°	30 per cent.	36°	71 per cent.

Summarizing the complete tables, which are omitted here for lack of space, we have the following results:

Maximum relative humidity, 45 per cent.; recorded November 4th, at 8 A. M. It had been raining during the night, the outside air was very damp, with an easterly wind blowing. The window was partly open and there was but little heat coming from the furnace. The relative humidity outdoors was 92 per cent. These conditions, of damp air outside, open window and small furnace fire, were clearly favorable for giving a high degree of relative humidity indoors. The humidity indoors at noon of this same day was also 45 per cent. The weather at that time was beginning to clear, with the wind gradually veering towards northwest. The window was still open.

Minimum relative humidity, 21 per cent.; recorded November 23d, at 10 P. M. Weather clear; northwest wind, moderate; windows shut and good supply of heat from the furnace. The relative humidity outdoors was 68 per cent.

Maximum relative humidity for a whole day, 40 per cent.; recorded November 19th. The day was overcast, damp and rainy, window open throughout the day and moderate heat from furnace. The relative humidity outdoors averaged 87 per cent, which was exceeded on two days only, namely, November 15th, with 91 per cent., and November 18th, with 90 per cent.

Minimum relative humidity for a whole day, 24 per cent.; recorded November 13th. The day was clear and cold, with a moderate to brisk northwest wind. The windows were shut most of the day and the temperature of the room averaged 67 per cent. The relative humidity outside on this day averaged 51 per cent., which was the minimum for any whole day during the period of observation.

The mean relative humidity indoors for the whole period was 30 per cent. Nine days had a relative humidity between 24 per cent. and 29 per cent.; ten had between 30 per cent. and 35 per cent., and two between 36 per cent. and 40 per cent. It will be seen by reference to the table that the mean relative humidity of the outside air during the same period was 71 per cent., or 41 per cent. in excess of that indoors.

The relative humidity in a room is clearly the resultant of several variables, among which are the temperature and humidity outdoors, the amount of heat coming from the furnace, the amount of evaporation from the evaporating pans, the extent to which the room receives the outside air through the open windows, etc. Probably the varying amounts of moisture absorbed and given off by the furnishings of a room also come into play, as suggested by Dr. Henry J. Barnes. It was hoped, as one result of the present study, to be able to determine roughly the relative importance of some of these different factors, especially of the effect of varying amounts of water evaporated from the evaporating pans, but this was found to be impossible, under the conditions of the investigation. It appears, nevertheless, from an examination of the data, that the relation between the relative humidity of the air outside and inside is fairly close, increasing relative humidity outside being closely followed by increasing humidity indoors, and *vice versa*. The weather conditions during which the absolute maximum of 45 per cent. and the daily maximum of 40 per cent. were noted were, as has been seen, precisely such as would have led one to expect high humidity indoors. On the other hand, the northwest wind with its dry, clear weather, which prevailed when the daily mean of 24 per cent. occurred, naturally preceded and accompanied low relative humidity indoors. These same relations appear distinctly on a good many of the days during which the observations were made.

In one case (November 4th) a change of wind from southeast to northwest, accompanied by clearing weather, was closely followed by a decrease in relative humidity of 34 per cent. outdoors and of 6 per cent. indoors. In another case (November 11th) a change of wind to the east, with rain, brought a rise in relative humidity of 15 per cent. outside and of 6 per cent. indoors. On a third occasion (November 12th), when a rainy day was followed by a clearing day with northwest wind, the relative humidity fell steadily from 32 per cent. at 8 A. M., to 30 per cent. at noon and 28 per cent. at 6 P. M., the decreasing humidity keeping pace with the decreasing cloudiness and increasing velocity of the dry northwest wind. The relative humidity outside fell from 78 per cent. at the first observation to 69 per cent. at the second and 63 per cent. at the third. The windows were closed at the time of all the above changes.

Now, the interesting question is: How did the relative humidity indoors compare with that of other places outdoors? It has been seen that the mean relative humidity in Cambridge during the twenty-one days of observation was 71 per cent., this value being based on the readings of the Richard hygrograph at the same hours as those at which the psychrometer observations were made indoors. The mean relative humidity in Boston for the year 1899 was 69 per cent., and for the month of November, 1899, 68.8 per cent., as kindly reported to me by Mr. J. W. Smith, local forecast official of the United States Weather Bureau in Boston. The lowest mean annual relative humidi-

ties in the United States are those for the Weather Bureau stations in the dry southwest. Yuma, Ariz., has a mean annual relative humidity of 42.9 per cent., with a mean monthly minimum of 34.7 per cent. in June. Santa Fé, N. M., has a mean annual of 44.8 per cent., with a mean monthly minimum of 28.7 per cent. in June. Pueblo, Col., has a mean annual of 46.2 per cent., with a mean monthly minimum of 37.6 per cent. in April. Death Valley, Cal., was found to have a mean relative humidity of 23 per cent. during five months (May–September) of the year 1891, when a temporary meteorological station was maintained there by the United States Weather Bureau. During this same period the mean temperature was 94°. In the dry interior of the great Eurasian continent we find the following relative humidities: Southwestern Siberia and Western Turkestan have a mean of 45–50 per cent. in July. Yarkand, in Eastern Turkestan, has a July mean of 47 per cent. In the arid region in the neighborhood of the Sea of Aral, Nukuss (lat. 42.5° N., long. 59.6° E.), has a June mean of 46 per cent., and a 2 P. M. June mean of 19 per cent. Petro-Alexandrowsk, a degree and a half east of Nukuss, in the desert (lat. 41.5° N., long. 61.1° E.), has a mean of 34 per cent. in June. Kasalinsk (lat. 45.8° N., long. 62.1° E.) has a mean of 45 per cent. in July. The air is still drier in the deserts nearer the equator. Ghadames, in Tripoli, has 27 per cent. in July, and 33 per cent. in August, and the Kufra Oasis has 27 per cent. in August, with a 3 P. M. August mean of 17 per cent., and 33 per cent. in September. In the Punjab and Northwestern India, Lahore has 31 per cent. and Agra has 36 per cent. in May.

These examples show clearly enough that the atmosphere of the room in which the observations above referred to were made was, and is, drier than that of many desert regions. That so dry an atmosphere is not healthy, especially in our winter climate, there is no need of an argument to show — certainly not in a medical journal. This low relative humidity means excessive evaporation from skin, lungs and respiratory passages. Furthermore, the strain which is put upon the body in the rapid adjustment which it has to make when we go out from the high temperatures and the desert aridity of our houses in winter into a temperature it may be 70°, 80° or 90° lower, and a relative humidity of 70 per cent. to 100 per cent., is a greater one than we ought to repeat day after day, and many times a day.

The present methods of heating our houses are wretchedly inadequate from the point of view of supplying sufficient moisture. Undoubtedly, the relative humidity of the air coming from an ordinary furnace may be somewhat increased by increasing the size or the number of the evaporating pans in the furnace, or by placing pans of water on or, better still, within the registers. As to the precise amount of increase in the relative humidity as the result of either of these methods, I am not as yet able to give any definite results.

After I had begun the observations whose discussion forms the subject of this paper I received from Dr. Henry J. Barnes, of Boston, a copy of an article by him entitled "The Arid Atmosphere of Our Houses in Winter," published in the *Transactions of the American Public Health Association* for 1898. The relative humidity of Dr. Barnes's office, as determined by observations, with the Mason hygrometer, during seven days in January, 1896, was 27 per cent., while that of the outside air was 73 per cent. This humidity accords closely with that of 30 per cent. found in my study. Dr. Barnes's office was heated by hot-air furnace, with water tank in furnace evaporating from one to two pailfuls daily. In Dr. Barnes's paper mention is also made of the results of humidity observations within other buildings in Boston. These results are here tabulated for purposes of comparison.

Place and Time.	How Heated.	Mean Relative Humidity Indoors.	Mean Relative Humidity Outdoors.
City Hospital, 7 days, December, 1878.	Indirect steam.	29 per cent.	71 per cent.
Office of Dr. Barnes, 7 days, January, 1896.	Hot-air furnace.	27 "	73 "
Office of Dr. Ayer, 10 days, February, 1896.	Indirect steam.	36 "	70 "
Women's Hospital, 8 days, February, 1896.	Indirect steam.	24 "	71 "
City Hospital, 12 days, February and March, 1896.	Indirect steam.	38 "	74 "
Means.		31 per cent.	71 per cent.

The mean relative humidity indoors derived from these five sets of observations was 31 per cent., which is one per cent. higher than the mean obtained by me in my study. The mean relative humidity outdoors was 71 per cent., which corresponds to the outside humidity during my observations. By means of his "humidifier," which is placed over the register of a hot-air furnace in his office, Dr. Barnes has been able to obtain a mean relative humidity of 53 per cent. This humidifier evaporates on the average 4½ quarts of water daily, and Dr. Barnes has found that with this higher relative humidity his office is comfortable at a temperature of about 65°, whereas, without the artificial supply of moisture, a temperature of 70° to 71° was necessary to make the room comfortable. I am indebted to Dr. Barnes for a reprint of his interesting paper, as well as for references to other writers on this same subject.

PSYCHOLOGY AND HEREDITY.[1]

BY ROBERT MACDOUGALL, PH.D., CAMBRIDGE, MASS.,
Instructor in Psychology, Harvard University.

(Concluded from No. 8, p. 189.)

MANKIND is beset as well in mature life as in the years of childhood by a host of fears, of which the majority have no ground or explanation in the nature of external circumstances. The fear of strangers — needless in our day of regulated society — the fear of beasts, eliminated as a practical factor by the destruction of wild animals; the fear of the dark, deeper than the tales of ill-advised nursemaids or pranks of foolish playfellows, and often ineradicable even in mature life, and the fear of open spaces, both of which point to a sometime existence when the shades were full of terror and the menace of the plain was to be avoided only by skulking in the thicket, — these, together with the thick cloud of still more monstrous fears with which the alienist must deal, the automa-

[1] Read at the meeting of the Boston Society for Medical Improvement, December 4, 1899.

tisms of childhood and youth, habits of stepping on particular flags of the pavement and avoiding cracks, counting and dividing manias, are forms of activity which stand apart from the purposeful stream of our conscious life and find no explanation in the facts of its present environment, but which become intelligible and significant in the light of a theory which views them as residual functions of the soul, which exist now because at one period they were active and fully developed responses to an environment which has since passed away.[14] These pathological feelings and abnormal forms of activity are doubtless of the instinct type, and their appearance is probably due to a process of ripening in the brain in virtue of which it becomes super-irritable to particular kinds of stimulation at successive periods in its development. The fact of conscious experience is thus made the correlate of a specific process of change in the nervous substance.

But the courses run by the physical and mental evolution of the human individual are not wholly parallel and synchronous, and I wish to point out several important aspects of this discrepancy.[15] In the first place, there is a difference in the amount of directive control which can be exercised over the distribution of nourishment during the formative periods of two life processes. The type of the physical individual is practically fixed by the close of the embryonic development. During the plastic antenatal period the changes which the organism undergoes are great and sweeping. The general conformation of body structure and its system of functions pass in successive stages through type after type of the taxonomic series,[16] and concomitantly with these changes the distribution of nutriment to the transient structures varies according as they are nascent or atrophent. But this distribution of nourishment in unequal ratios to the permanent and transient tissues is neither under human control nor determined by a changing environment, but is due to a pre-existing hereditary disposition to a particular direction of development. It is impossible to control the supply of nutriment to particular parts of the growing organism on account of the intermediation of a transforming and administering agent in the mother's body, and were this obstacle removed there would remain the more fundamental one that the same chemical elements and compounds are distributed throughout the whole extent of the organism, and that therefore the withrawal of any element or group of elements from the food supplied would be represented by a reduction of the total vitality or a disturbance of the general functioning instead of being confined to specific organs or tissues, for the effective agent of distribution lies in the hereditary constitution of the organism itself.

In the psychic individual, on the contrary, the process of growth, instead of being protected from disturbances of a pre-established equilibrium, is dependent upon the irregular stimulation of a changing environment, which is to a great extent directly controllable by human agencies. The life of consciousness begins with the independent physical existence of the individual. Whatever be the earlier strivings of sentience in the embryo, the change of conditions at birth is so tremendous, the new environment so significant for all subsequent activity, that we rightly call this the birth of the soul. Structurally and functionally the whole complex system of psychological activities up to this point was an existence *in potentia*, consisting of an aptitude or tendency to perceive and react in a specific way under any given conditions, and the realization of these implicit capacities stands in an intimate relation to the world in which the organism is placed. For we must recognize two essential factors in the development of the concrete consciousness, namely, an internal impulse to react and an external something upon which reaction shall take place. Fit nourishment in the shape of a suitable environment must be provided if any given form of activity is to become part of the individual life, for the inner factor is not a full-blossomed habit or function, but only a propensity to act in a specific way when the right conditions for its discharge are found. To transform the instinctive tendency into an established function, it is absolutely necessary that the complete reaction demanded by the impulse just struggling into life should be successfully carried through. Feed the instinct, it thrives; starve it, it dies. This is illustrated in the changed habits of birds and beasts kept in captivity.[17]

The psychic individual therefore stands in a decidedly different relation to the changing conditions of life from that which the physical organism presents. His development may be quickened, directed or retarded by manipulation of surrounding conditions. For as a matter of fact this environment is neither a stable one nor one in which the changes are presented fortuitously or independent of human control. The relation of nourishment to specific structural and functional development is known, and the supply can be, and customarily is, unequally distributed for the purpose of fostering or repressing the various propensities which manifest themselves. We have therefore to acknowledge the reality of a world of design within the psychological life and the direction of its process of change in subservience to ideal ends. This agency, however, produces nothing; its function is purely selective, controlling the process only by supplying material for the desirable impulse to react upon, and witholding it from the undesirable. "There is a happy moment," says James, "for fixing skill in drawing, for making boys collectors in natural history, and presently dissectors and botanists; then for initiating them into the harmonies of mechanics and the wonders of physical and chemical law. . . . If a boy grows up alone at the age of games and sports, and learns neither to play ball, nor row, nor sail, nor ride, nor skate, nor fish, nor shoot, probably he will be sedentary to the end of his days; and, though the best of opportunities be afforded him for learning these things later, it is a hundred to one that he will pass them by and shrink back from the effort of taking those necessary first steps the prospect of which, at an earlier age, would have filled him with delight."[18] This directive and inhibitive control of the environment reaches its chiefest significance in the ethical life, for the fundamental fact of moral training lies in the reinforcement of the good impulse by affording it every possible occasion for functioning upon the fullest and richest material,

and the elimination or repression of the evil by a literal process of starvation.[19]

But, further, there is a positive side to this process in which also it differs from that of organic evolution. The physical individual is given practically complete at birth; there are no further organs to be added, few new structures to develop later. The withdrawal of nourishment from any one part is then a reduction in the total sum of elements making up the individual. If a limb be found so that circulation ceases, growth is arrested, the member atrophies, and the body is mutilated; it is just so much withdrawn from a limited sum.

Both physically and mentally men are bundles of life, all roughly of the same size; they have the same assimilative and reproductive functions, have like perceptive apparatus, and make similar reactions; each can realize only a certain number of activities, possess a certain limited store of knowledge, and set of interests knit up in his life. But these do not represent all the inherited tendencies which his nature contains. The individual is potentially, that is, as a transmitting agent in the chain of life development, immensely more than he can actually become. This has been expressed by the term pre-potency. Eyes, hair, features, color sensitiveness and color blindness, traits and gifts of mind characteristic of the grandparent may appear in the grandchildren after skipping over the intervening generation. Here we must suppose the trait to have existed in that link in some form as a transmissible and developable tendency. It may be that we should say the individual represents all the possibilities of all his ancestors. Though only one color of eyes, which we may call the dominant tendency in that individual, can be physically realized, yet all are there — blueness, grayness and blackness — as transmissible tendencies, which may find a theatre of realization in some future generation. When the characteristic has been submerged a sufficient length of time, its reappearance will be amidst modified forms and new habits, as is illustrated in the occurrence of atavistic traits and reversions to more primitive forms of body structure, of feelings, of instincts, and the like, which are presented in the course of certain diseases, and by the patients in our hospitals for the insane.[20]

Now, this pre-potency, which, with the exceptions just mentioned, has already ceased at birth to be a real, physical pre-potency, continues to be a living factor in the psychic development, and presents a field where the process of structuring can be directly modified and controlled. The fact should lead to a broad hopefulness in our educational activities and impress upon us the need of providing means and opportunity for the development of the child in all desirable directions whether these represent the actual endowment of the parent or not. Our conception of the possibilities of education are vastly different if we regard the child as the reproduction of his parents, limited in his aptitudes strictly to those which their lives have presented, or conceive him to be the exponent of a stock of which both parents and offspring, as concrete individuals, are but incidental offshoots, drawing their characteristics alike from the common well of inheritance, of whose contents each life can bring to the surface but a few meagre drops.

The psychical individual, therefore, is in a much more intimate fashion the outcome of his environment than is the physical. And to this must be added the presence of a wholly new and immensely insignificant factor in so far as concerns the kind of thing which the individual consciousness is to become as over against the kind of stock to which it may belong. This is the reality of the inheritance of acquired characteristics in the world of consciousness. The fact of cumulative heredity through the transmission of the results of use and disuse needs but to be indicated. The sum of the father's acquisition is transferred to the child not by any devious or obscure process, laying the whole matter open to doubt, but by direct and immediate communication. Our knowledge is neither inherited nor acquired; it is socially transmitted, and we who stand in the foremost files of time are indeed heirs of all the ages. But the path of transmission has completely changed, a new form of heredity here makes its appearance; for the acquired characters instead of being stored in the organism are laid up in the environment and transmitted through it. In song and story, in oral tradition and printed book, in pictures scratched and woven and painted, in temple and tomb, in implements and clothing, in weapons of war and instruments of precision, in systems of science and philosophy and religion, are treasured up the results of the struggles and conquests of our forefathers over their physical and spiritual environment, and we are inheritors of their wisdom profiting by every item of their winnings. The process of evolution in the individual organism is directly conditioned by the nature of the world in which it exists. Adaptation cannot outrun the environment. The organism may present as many variations as you please fitted to survive under conditions which in the plan of the universe are to be realized next century or next æon, but it is none the less unfit for the present and is as subject to elimination as is one fitted to conditions gone by a thousand ages or utterly non-existent. The environment sets the pace, and the process of organic adjustment always lags a step behind the process of change therein. Now in the psychological individual this pace is tremendously increased. For here man creates his own environment, which consists, through all its significant sweep, of the stored-up results of past activities. Under this increased pressure, therefore, we should expect a great acceleration in the process of adaptive change. In one regard at least this expectation is justified. In the individual life produced under these new conditions, the type manifests an amazingly successful adaptation. It is only occasionally that the force of this fact pushes in upon us and we realize how greatly in the conscious life the process of evolution is foreshortened. The things we see and handle and do, our pleasures and our pains, the practical activities of our life and its intellectual interests, the procession of events in the world, yet about us and of images in our own consciousness, are inconceivably different from those of the primitive man. We have done away with his whole intellectual heavens and earth, and though the physical laws under which he existed still endure, as well as all the grander features and processes of the world, yet in their psychological values as objects of reaction, as motives for the will, the transformation has been no less great than in the

[19] R Schäfer: Die Vererbung: Ein Capitel aus einer zukunftigen psychologischen Einleitung in die Pädagogik. Berlin, 1886.

[20] Chief among facts of latent heredity are those of secondary sexual characteristics. See Darwin: Variation of Animals and Plants under Domestication, vol. ii (second edition), 1892; and Galton: Natural Inheritance, p. 134.

realm of imagination and belief. And this holds true not of a few favored individuals alone, but of the race as a whole whenever these new conditions are imposed upon it. You will note that the genius does not represent this crest in the wave of development; he is a sport, a variation not accounted for by any environment definable by us.

But the further question remains as to the security of this advance, the stability of the latest type developed. Transformation of the individual may not affect the stock itself. The high degree of specialization presented may be wholly dependent upon this exceedingly artificial environment, that is, an environment which is composed not of elements resulting from a natural process of objective change, but consisting of the products of transformation within the individual organism itself — a subjectively objective environment. The wild flavor may still be there, though continually suppressed in the individual by the presence of these secondary selective conditions, and may be ready the moment these conditions are broken down to assert itself in a reversion to more primitive, savage forms.

I think this statement of the case is true. The variety which we call the scholar, the man of culture, the scientist, is a highly unstable type insecurely maintained upon a foundation of more primitive attitudes which represents the fundamentally real type still. In so far as the conditions which determine the nature of the present concrete individual life consist in these accumulated results of acquired characteristics stored in the environment and transmitted by social heredity, they are transient and directly ineffective for racial variation. They form only a scaffolding about the life. I do not believe that the effects of intellectual training, or artistic culture, or acquired manual dexterity, or business sagacity, in so far as they are training effects and not spontaneous variations, are reproduced in the form of permanent variations of type.

But indirectly this artificial structure does affect the racial adaptation in that it is a pre-potent agent of selection over and above those which the untransformed environment presents, and therefore fosters the preservation of those variations which lie in the direction of its own change. In so far as those sports arise which we call the saint, the genius, the man of feeling, this environment tends to preserve them, but by a purely selective, not a productive, activity. Here, indeed, lies the great significance of the Weissmannian-Spencerian debate. Our interest in it is at heart a psychological one and no other. Not only does the moral aspect of the problem touch us more closely than the physical, but the facts in the latter case are much less ambiguous than in the former, for the physically bad stock tends toward elimination, the physically good toward survival. But such an easy optimism is by no means possible on the spiritual side. The morally bad stock shows no less fecundity than the good. The idle, the shiftless, the dull, as perhaps also the criminal, propagate more rapidly than the rest of the race, rather than less so, if for no other reason than that the restraints upon marriage are much less rigidly observed by them than by the more highly selected members of society. The moral problem is absolutely different according as we hold to one or the other of these two views. For the Spencerian training is of more than individual value; the effects of use and disuse are inherited, and the cumulative results of right thinking and right living in the end convert bad stock into good stock. Restraint, discipline, the conformance to a higher life, are fundamentally hopeful, since the process of moral training tends to supersede itself by effecting an adaptation of the race as a whole. Under the Weissmannian concept there is no hope and no end to the process; its labors are Sisyphean, for the effects of training are transient and individual. The bad stock is no more got rid of by discipline and culture than are the impurities of a river by filtration of the water on the part of those living below the source of pollution. We are presented with a complete realization of the Calvinistic doctrine of predestination to good and evil. The units of good and evil under the former concept are individual impulses within the single human consciousness; moral progress is the selection and preservation of the right and good aptitude and the elimination of the evil; the selective agent is the individual human personality; and the result is a purgation and transformation of human society through the moral culture of that personality itself. Under the latter concept these individual human consciousnesses themselves are the units of good and evil among which selection is to be made; moral training is indeed still endlessly valuable so far as the single human subject of it is concerned, but racial progress can be made only by preservation or destruction of the good and evil souls themselves; and the agent of selection is no longer conceivably the individual — the function of control and direction must lie in the hands of that human society which is itself in process of transformation. If this be the true nature of the process,—

"So careful of the type it seems,
So careless of the single life,"—

I leave it to you to consider what readjustment of attitude must be made, what reconstruction of one's whole conception of responsibility and duty toward oneself and the world at large.

Clinical Department.

PERINEPHRITIC ABSCESS INVOLVING THE APPENDIX.

BY HUGH WILLIAMS, M.D., BOSTON,
Formerly House Surgeon, Massachusetts General Hospital.

THE patient, a young man of twenty-four, was brought to the Massachusetts General Hospital, May 1, 1899, during the service of Dr. M. H. Richardson, and was operated upon by Dr. J. G. Mumford. The man was sent in with the diagnosis of appendicitis by his attending physician.

The patient's previous history was good, and he stated that he had always enjoyed good health up to the time of his present illness. He was a well-developed and well-nourished man, and gave the following history: About ten days previous to his entrance to the hospital, he had been taken with pain in the abdomen and back — not localized, and coming on suddenly. The next day he had headache, felt weak and nauseated, and vomited soon after, and since then, up to the time of his entrance, he had been unable to retain anything on his stomach. The pain, which had continued from the first, had been getting more severe,

and was now localized, extending from the umbilicus to the right loin and into the back. The bowels had been constipated. His physician stated that there was high fever during the first few days of the illness, but that since then it had gradually fallen to normal, and had remained so since. The urine was said to have been high colored and diminished in amount, but no chemical examination had been made of it previous to his entrance.

The general condition of the patient was fair, with a temperature of 98.6°, pulse 84, and respiration 18. The abdomen was generally but only slightly distended. There was marked rigidity of the abdominal muscles on the right side. A large mass could be palpated in the right loin, but its limits could not be followed out on account of the extreme tenderness. The dulness on percussion was continuous with the liver dulness above, and extended below to the anterior superior iliac spine. There was dulness in the flank, extending forward to just external to the border of the right rectus muscle. Rectal examination was negative. The blood count showed 14,000 white corpuscles. There was no evidence of edema anywhere, and the examination of the heart and lungs was negative. The diagnosis of appendix abscess was made.

The patient was prepared for immediate operation, and under ether a mass could be readily palpated, extending from the costal margin to below the anterior superior iliac spine. An incision about four inches long was made along the border of the right rectus muscle, the general peritoneal cavity opened, and the intestines walled off with gauze from the mass, which was then opened, evacuating several ounces of foul-smelling pus. Three small pieces of tissue were then removed from the abscess cavity, each piece about the size of the terminal phalanx of the little finger, which on section, macroscopically, looked like renal tissue, but whether they came from the kidney proper in a condition of extreme lobulation or were supernumerary kidneys was not determined. No part of the appendix was found. The abscess cavity was then washed out, and gauze wicks inserted. The patient was in very poor condition at the end of the operation, but reacted well to stimulation.

On the third day after operation, the discharge from the wound had a strong urinous odor. On the ninth day a fecal fistula was found in one of the loops of bowel presenting in the wound, and besides this fecal discharge there was a discharge of a thin fluid, having a distinct odor of urine from the upper part of the wound. A few days after this the patient began having pain in the rectum, and at times severe rectal tenesmus, and at the same time his temperature shot up. Rectal examination showed a large fluctuating and tender mass on the right side of the pelvis. This was aspirated on the sixteenth day after operation and a considerable amount of pus evacuated, giving immediate relief, the temperature falling to normal the following day. There was no longer any urinous discharge from the wound at this time, but the fecal fistula had increased in size. The wound was otherwise clean and healthy looking and granulating up rapidly. The twenty-four-hour amount of urine, which had been steadily increasing, was now normal. The general condition of the patient had meanwhile rapidly improved, and a firm cicatrix having formed about the fecal fistula, he was again operated upon for its closure by Dr. S. J. Mixter on the 22d of June.

In this operation, a stump of the appendix, about one inch long, was found lying to the right of the cecum. It was surrounded by a mass of firm adhesions, showing that it must have been either involved in the previous abscess, or that it was its primary cause. The right kidney was carefully examined and found to be apparently normal in every respect, and not lobulated, showing that in all probability the kidney tissue removed at the first operation was of supernumerary origin. The adhesions having been freed, and the opening in the bowel closed, a small gauze wick was inserted, and the abdominal wound closed. The patient made an uninterrupted recovery, the wound having entirely closed three weeks after operation.

The microscopical examination of the pieces of tissue removed at the first operation showed them to be renal tissue, part of which showed replacement with granulation tissue, as if forming the wall of an abscess cavity. The pathological diagnosis was, "a destructive suppurative inflammation of the kidney of rather long standing."

Repeated examinations of the urine showed it in every case to have been normal. This seemed to be another reason for considering the kidney tissue removed of supernumerary origin, and the right kidney itself to be normal. Whether the abscess was primarily due to inflammation about the kidney or about the appendix could only be settled by the pathological report, which stated that the inflammation about the kidney was of rather long standing. If we take this view, we can then consider the appendix to have become secondarily involved, and that at the time of its involvement the acute symptoms began.

Medical Progress.

REPORT ON ORTHOPEDIC SURGERY.

BY E. H. BRADFORD, M.D., AND E. G. BRACKETT, M.D., BOSTON.

CONGENITAL FLEXION OF THE KNEE.

M. Phocas[1] reports six cases of this rare condition, one with an account of the dissected leg, and reviews the previously recorded cases. The cause of this condition, in which extension at the knee beyond a right angle is impossible, is obscure. It occurs usually in the children of primiparæ. Other deformities may also be present, as flexion or adduction of the thigh, knock knee, and very commonly club foot. The so-called "scars" often attributed to amniotic adhesions are common. Anatomically there is a sharp anterior bowing of the femur near the epiphyseal line, and obliquity of the upper surface of the tibia, sometimes a displacement outwards or an absence of the patella, and possibly a deformed head of the fibula. In addition to these bony changes all the soft parts on the back of the leg are contracted, ligaments, muscles, fasciæ, and skin. Treatment should be directed to a gradual stretching and correction by manipulation and appropriate apparatus or by immediate osteotomy and tenotomy.

ACQUIRED DEFORMITIES OF THE TOES.

M. Kirmisson[2] suggests that, in addition to im-

[1] Revue d'Orthopédie, January, 1899, p. 14.
[2] Loc. cit., March, 1899, p. 133.

proper shoes, there are many causes for hallux valgus and allied deformities of the toes. He mentions particularly rheumatism, alcoholism, various diseases of the nervous system, defects of ossification, and a congenital predisposition in certain cases.

SUDDEN DISLOCATION SECONDARY TO ACUTE DISEASE.[3]

Of 81 cases of this rare complication 32 followed typhoid, 24 followed acute articular rheumatism, 13 followed scarlet fever, and the remainder variola, gonorrhea, grippe, erysipelas, and "eruptive fever." He reviews different theories which have been presented to explain the pathological conditions and occurrence of this form of dislocation, and particularly that of the hydarthrosis of the joint by Petit, and that of the muscular action by Verneuil, and considers these at length, particularly in regard to the fallacies of the theories and more especially in regard to that of Petit, that of the hydarthrosis, which has received the most support, and is regarded by the modern writers, among whom are Keene, as the probable one; and third, the theory of the combined forms of the hydarthrosis and muscular action. The hip-joint is almost invariably the one involved, although in rare cases the knee, shoulder, or other joints may be affected. It occurs usually in young patients of either sex during convalescence, and is characterized by the absence or slight extent of any bony or cartilaginous changes. When associated with such changes tuberculosis must be considered. The accident is probably due to a combination of causes, chief among them being the long continuance of faulty positions, the weakening and stretching of certain muscles and ligaments, the distention of the capsule by effusion. In this condition any slight reflex muscular spasm may cause a dislocation. The accident usually produces no symptoms other than the characteristic deformity, although it may cause great pain, or, again, relieve pre-existing pain. Epiphyseal separation is to be excluded. Reduction under anesthesia is usually easy, especially if done promptly. Kirmisson recommends the following maneuvres: First, complete flexion with persistent adduction, to be followed by circumduction; then with the leg abducted, semiflexed and rotated outward, the head will slip quietly into place. If manipulation fails continued extension and, if necessary, tenotomy should be tried. After reduction the leg should be held in the abducted position with extension, if necessary. Excision or osteotomy may be necessary in immediate cases.

SUDDEN DISLOCATION IN HIP DISEASE.[4]

These rare accidents, comparable in some respects to dislocation after acute diseases, occur usually early in the course of the disease, before extensive destruction of the joint surfaces has occurred, and usually without suppuration. They are very different from the slowly progressive luxation due to erosion of the femoral head and acetabulum as the result of prolonged disease. Owing to the slight joint changes reduction under an anesthetic is usually possible and permanent.

ERRORS IN SKIAGRAPHS.

Hoffmeister[5] calls attention to the difficulty of determining the meaning of the Röntgen ray pictures, and considers that it is necessary in order to get a correct opinion of an x-ray picture to have correct data in order to know what the proper projections of the portion of the body were. This is particularly true of skiagrams of the pelvis, and it is necessary in these to have the position of the lamp, the body, and the plate accurately given.

CONGENITAL SCOLIOSIS.[6]

The author quotes the statement of Coville that one case of scoliosis was to be found in 1,015 newborn children. He himself mentions two cases, one after a forceps delivery and where death followed pneumonia. The pathological specimen showed a left convex dorsolumbar curve, with a right cercivodorsal convex curve, with marked rotation and without any change in the vertebræ. The curve he considers to be the result of compression *in utero*.

SCIATIC SCOLIOSIS.

Denuce[7] reviews the various opinions which have been advanced in regard to the causation and development of this deformity following painful affection of the sciatic nerve, and states the ground for his own belief that this condition first seen does not exist. The distinction made is more or less of a technical one, but is of value in that it is a careful check on the sometimes hasty grouping of cases on superficial resemblance. He lays stress on the recognition of the necessary condition in true scoliosis, in the existence of the deviation of the spinal column, and greater or less permanency of the deformity. In many of the cases so classed, he thinks that there existed previously a scoliosis, exaggerated temporarily by the distorted position, and many of the others being cases of sacro-iliac disease, the common symptoms of which is considered in the article in detail. It concludes that, (1) sciatic scoliosis does not exist; (2) that sciatica, like any painful affection of the leg, tends to the assumption of a malposition of the trunk in leaning toward the affected side and a corresponding depression of the pelvis, and results from the effort to maintain the equilibrium, but this position is not permanent, may be reversed, and does not constitute true scoliosis; (3) the existence of a more or less fixed lumbar spine, and lateral inclination of the trunk, with a sciatica, should lead one to suspect the primary condition to be a sacro-iliac disease.

CONGENITAL SPASTIC PARALYSIS.

Hoffa[8] considers that the origin of this affection is an intrameningeal or an intracerebral hemorrhage, most frequently caused by a difficult birth, and causing an injury to the neurons of the motor tract. This lesion is manifested not in a complete interruption, but in an injury of the function. As a rule, the extensors and abductors are weaker than the flexors and adductors. Treatment consists in increasing the energy of the cortical motor neurons, and diminishing the activity of the peripheral neurons. The first must be developed by massage, gymnastics and resistant movements. Tenotomy and tenectomy are indicated in the stiff muscles, followed by fixation.

THE PATHOLOGY OF CEREBRAL PARALYSIS IN CHILDREN.

Schultess[9] had the opportunity to observe two children who presented this condition at an early age, one being fourteen days old, and the other three weeks. In these instances the characteristics seen in older children were well marked, pointing to a congenital origin of all cases of this class. In a few older cases a lengthening of the ligamentum patellæ was observed, a result of the exaggerated flexed position, in the opinion of the writer. The treatment recommended is that of tenotomy of the tendo Achillis, with forcible correction and flexion in a plaster bandage, with massage later, and the use of apparatus where it is necessary.

CEREBRAL PARALYSIS OF CHILDREN.

Bocker[10] classifies cervical paralysis as follows: (1) That affecting the lower extremities only, true Little's disease; (2) those affecting the upper extremities also, with cervical disturbance as well; (3) cases where there is athetosis present as a prominent symptom; and (4) where there is cerebral hemorrhage. The prognosis he considers bad in the second class. Cases of the first class are most favorable from an orthopedic point of view. Massage of both the weak and the spastic muscles may accomplish a good deal, but tenotomy or tenectomy is of more benefit, followed by massage, exercise and apparatus. Athetosis is to be handled by massage and gymnastics twice a day, carried on for six months. In cerebral hemiplegia the treatment is much the same as far as the legs are concerned. For the arm, a transplantation of tendons is of service. Transplantation of tendons is also of use in some foot cases, bending of the bone due to inflammatory softening.

THE SURGICAL TREATMENT OF CONGENITAL SPASTIC PARALYSIS.

Lorenz[11] recommends for treatment tenotomy or tenectomy in the severer cases, followed by fixation in an over-corrected position. In the severe cases of spasm of the adductors he has resected the obturator nerves. The after-treatment he considers of the utmost importance. This consists of massage, gymnastics and faradization. Treatment by orthopedic apparatus is not found of assistance.

OPERATIVE TREATMENT OF RADIAL PARALYSIS AND TENDON TRANSPLORATION IN SPASTIC PARALYSIS.

Franke[12] describes a number of operations on the upper extremity. The tendon of the extensor carpi radialis longus was shortened, and with the end forcibly thrown back, the central end of the divided tendon of an active flexor carpi ulnaris was sewn into the tendon of the extensor communis digitorum. The result of the operation was very good. Arthrodesis of the shoulder-joint was done in one instance to prevent the inward rotation of the arm. The author is of the opinion that there is no incurable radial paralysis. In spastic paralysis the author combines tendon transplantation, tendon lengthening, and tendon shortening.

TENDON TRANSFERENCE.[13]

The author advises this procedure not only in cases of infantile paralysis, but also in cases of cerebral paralysis. An examination before operation should be made by voluntary innervation of the muscles, and by electric testing. Where some doubt remains it is better to make the incisions long enough to see the lower ends of the muscles, and in that way determine on their quality. It is best not to transplant the active muscle or its tendon, but to transplant the peripheral end of the paralyzed muscle on to the sound one, or split the tendon of the sound muscle and attach to the useless tendon. It is found necessary to lengthen tendons as well as to transplant. The question of the re-establishment of co-ordination seems not to be settled as yet. Practically, however, good results are obtained even from transplanting antagonist muscles. The following transferences are reported:

(1) The outer half of the tendo Achillis to the tibialis anticus in a traumatic case, without great gain.

(2) The flexor carpi ulnaris to a paralyzed extensor communis digitorum in cervical paralysis, with a shortening of the extensor carpi radialis. A second operation was performed, transplanting a paralyzed triceps into the deltoid, with a good result from both transplantations.

(3) A tenotomy of the adductors and hamstrings and later a transplantation of a half of the tendo Achillis to the paralytic extensor communis, with an excellent result.

(4) Ischioparalysis following attempt at violent reduction in double congenital hip with a perineal paralysis remaining, and a transplantation of the outer half of the tendo Achillis to the tibialis anticus; a good result.

(5) A paralysis equinovarus with a transfer of half of the tendo Achillis to the tibialis anticus; a good result.

(6) In cervical paralysis, shortening of the extensor carpi radialis, with good result.

(7) Infantile paralysis with dropping of the toes; transference of half of the tendo Achillis to the tibialis anticus; improvement of gait followed and voluntary dorsal flexion possible, but the foot was drawn out.

(8) Infantile equinus. The transference of the tendon of the tibialis anticus to the extensor communis digitorum; almost perfect result.

(9) Transference of the tendon of the rectus femoris, which was cut across and the peripheral portion was transplanted on the sartorius; little benefit resulting.

(10) Cervical paralysis of the musculospiral group; the extensor carpi radialis was shortened, with an excellent result.

(11) Infantile equinovarus with paralysis and contraction. The tendo Achillis was split and lengthened; the tendon of the extensor digitorum was exposed and the peripheral end cut, and the cut peroneus longus and tibialis were fastened to it. The deformity was corrected, but no active dorsal flexion followed.

(12) Paralysis equinovarus; shortening of the tibi-

[13] Goeht: Zeitschrift für orthopedische Chirurgie, Band vii, H. 1, p. 54.

alis anticus; the tendo Achillis split and fastened to the peroneus longus; good improvement followed.

(13) Flexion of the knee in an equinovarus from infantile paralysis. The tendo Achillis was split and a half of it sewn to the extensor communis digitorum brevis, with a good result.

(14) Infantile paralysis with contraction on the right and left side. On the right side the peripheral end of the peroneus longus was fastened to the tendo Achillis, and the same was done with the peroneus brevis; the tibialis anticus was shortened; on the left side only the tibialis anticus was shortened. The result was good position for both feet and active movements.

(15) Paralysis following fracture of the elbow. The extensor carpi radialis was shortened. The flexor carpi ulnaris was freed and fastened to the extensor communis digitorum. The result was a remarkably good one.

(16) An infantile flat foot. The tibialis posticus was shortened and a half of the tendo Achillis fastened to the tibialis anticus. The result was useful, but there was a tendency to over-correction.

(17) Paralytic valgus. The peroneus longus was cut and carried beneath the tendo Achillis and fastened to the tendon of the paralytic tibialis posticus. The result was fairly good.

(18) Infantile paralysis with the equinovarus. Half of the tendo Achillis was fastened to the paralyzed peroneus and the tibialis anticus was shortened. Good position followed, but no active movement.

(19) Paralysis of all the calf muscles and part of the quadriceps with an equinus position. Tibialis anticus was shortened and the position was improved.

A thorough asepsis is important as well as a correction before the operation. A definite plan is to be laid out on the basis of an examination of the limb, and either a transference of the active muscle to the tendon of the paralyzed muscle or *vice versa* is to be done according to the case. The contracted tendon is either to be cut or plastic lengthening done. The limb is to be fixed in a plaster-of-Paris bandage after the operation and allowed to get up in from one to two weeks. Plaster is to be worn four to eight weeks in all, and an apparatus is used afterwards, or a rubber band fastened by adhesive plaster to the upper part and to the shoe at the lower. Massage, electricity, and active movements are important; pure passive motion is of less value and can usually be omitted.

TRIGGER FINGER IN THE GERMAN ARMY.

Schulte[14] describes nine cases, five observed by him. In four cases an enlargement of the size of a pea could be felt in the affected hand; in one, a roughness easily noticed. This unevenness was to be observed in the portion of the hand between the line of the fingers and the middle of the hand, and was most noticeable at the point of check motion, disappearing in the middle point of the hand when the obstruction was overcome. The check was always seen in the direction of extension of the fingers and not the reverse. Schulte made a number of experiments on the cadaver, sewing pieces of sponge on the surface of the flexor tendons. This produced a difficulty in motion, but did not give the characteristic jerk. When, however, a thread of silk of medium thickness was knotted, the characteristic jerk and snap were observed. After careful dissection Schulte could determine that the check to the entrance of the knot was as the tendon played into the strong ligamentous arch, forming the sheath of the tendon. When this was cut the motion was easy.

[14] Deutsche militärärztliche Zeitschrift, 1897.

CONTRACTION OF THE HIP-JOINT AND ANCHYLOSIS.

Blencke[15] pays special attention to the correction of the shortening by an oblique subtrochanteric osteotomy, correcting the shortening by a practical lengthening of from five to 11 centimetres. He mentions a case of Landerer where a practical shortening of 16 centimetres was reduced to two and one-half centimetres. He mentions that slight amount of motion may be obtained after excision and after pelvi-trochanteric osteotomy of Lorenz, by interposing a muscular layer between the cut bone.

OBLIQUE TROCHANTERIC OSTEOTOMY.

Berger[16] recommends for correction of the deformity following hip disease an oblique osteotomy. Phocas[17] prefers the linear osteotomy. Nelaton also employs an oblique osteotomy, though he recommends that this procedure should not be undertaken until three months after an attempt to loosen the head of the femur by force.

AMBULATORY APPARATUS FOR HIP DISEASE.

Wieting[18] recommends suspending the patient and applying a short trunk hose of felt similar in shape to bathing drawers, with the addition of traction on the leg by adhesive plaster straps. A plaster spica is next applied, with especial care to make it firm and well fitting beneath the tuberosity and as far down as the knee. A steel pattern with side irons, with notched cross pieces on the top, is fitted on the plaster bandage and secured in place by the bandage. When this is done, the extension straps are transferred from the pulley to the side irons and fastened to secure proper dragging. He claims that in this way a better fitting apparatus to the pelvis is given than if the same dressing is applied in the horizontal position.

B. Scharff[19] states that a number of published cases are quoted, but many of these, in his opinion, result from osteomyelitis, which he regards as much more common than the literature would indicate. He reports three cases of his own and considers that the causes may be (1) osteoporosis accompanying osteomyelitis or accompanying tuberculosis, and (2) interference with the epiphyseal growth at one side of the epiphyseal junction, and (3) a rarefying ostitis following operation due to trauma.

ORTHOPEDIC APPARATUS.

Dollinger[20] claims that in tubercular disease of the hip-joint distraction and fixation are to be considered as the hygienic conditions favorable to cure. Traction in bed not only distracts but fixes. The relief from pain, however, he considers to be due rather to the fixation than to the distraction. Traction is of service in correcting deformed positions of the joint, but for the correction of deformity, the author prefers

[20] Loc. cit., p. 1.

gentle manual correction with repeated plaster-of-Paris bandage fixation, changed every three or four days. In affections of the spine head support is applied in all diseases above the seventh and eighth dorsal. At night the patient sleeps on a half shell of copper moulded over a plaster mould on a plaster jacket. In the daytime a plaster bivalve apparatus is used with a head support when necessary. In low lumbar disease a corset made of a light frame of metal with cross pieces in front over the chest, reaching from the upper part of the sternum to the pelvis, without pressure over the abdomen; and in the back a light frame on either side enclosing a lower central portion. For hip disease there are two forms of hip splint used, a short fixing thigh and pelvis apparatus and a long perineal crutch. In poor patients a plaster spica is used. In affections of the knee a fixation apparatus is used, but the perineal crutch is not. In fixations of the ankle-joint, a leather and metal support is applied with an arrangement by which the weight is borne upon tibial tuberosities, the heel being slightly raised.

RESECTION OF THE SACRO-ILIAC SYNCHONDROSIS.

Heyden[21] reports on the operative treatment of inflammation of these articulations, especially in tubercular affection. Twenty-eight cases were operated upon by Schader, the affected portion being removed by chisel. Of these 28, 11 were healed, three improved, 11 died, and one remained unhealed.

CHANGES IN THE VERTEBRÆ IN POTT'S DISEASE.

Menard[22] in an exhaustive study of specimens calls attention to the folly of speaking of a cure in Pott's disease after any short course of treatment. Study of sections shows foci capable of setting up active disease, where in the uncut specimen there seems complete consolidation. The number of vertebral bodies involved in a knuckle is seldom realized. The number, always at least as many as the spinous processes in the knuckle, may be six or eight without preventing the contact of the anterior edges of the vertebral bodies just above and below the diseased area. Thus the deformity is angular in front only; posteriorly the spinous processes are arranged like the ribs of a fan, while above and below in the compensatory curves the reverse may be true. The length of the knuckle varies with the number of bodies involved; the sharpness with the completeness of the folding forward, which may be only moderate even in cases of long standing, particularly in the dorsal region, owing to the ribs, but which is apt to be most extensive in the upper dorsal region. In the cervical region the pedicles and transverse processes may hinder the folding foward. A sequestrum may also hinder the infolding.

The mechanism of the deformity varies considerably. As a rule in the dorsal and lumbar regions the upper segment slips backward on the lower, then as the bending forward increases the bodies of the upper segment press on the lower and themselves ulcerate. Finally the upper segment settles forward. In certain cases lateral subluxation may occur, but the reason for this is not evident. While the bending forward may lead to a certain amount of ulceration of the bodies from pressure, and thus cause an increase in the deformity, it must not be forgotten that very often the disease progresses entirely independently of pressure, and that the destruction of the bodies considerably precedes the kyphosis. In connection with the relatively prominent dorsal and relatively small lumbar knuckles, the difference in the sizes of the bodies in each region is suggestive.

While usually the most extensive disease occurs in improperly treated cases, this is not always true. Patients may live with a remarkable amount of destruction, even of ten or eleven bodies. In certain cases in old people there may be a superficial subperiosteal erosion of the bodies for a long distance above or below the focus. In young people double foci are more apt to be found, which may later unite. While consolidation is going on in one place, the disease may be extending in another. It is not at all rare to find tuberculous disease of other joint bones or viscera associated with Pott's disease.

Coincident with the destruction of the bodies certain changes occur in the posterior arcs. The firm spinous processes are very rarely diseased, the pedicles which are nearer the bodies and made up of more spongy bone may be involved by the extension of the disease. The articular processes become the fulcrum, by which the vertebræ are in contact. The top of one articular process presses upon the middle of that above. Thickening and ulceration of the cartilages follow as a result of the abnormal pressure. Bony contact and ultimately bony union may occur, which may in time extend to the laminæ and spinous processes. Meantime, owing to the loss of the anterior attachments, there is a slipping backward and settling of the posterior area. This is greatest in the lumbar, where the laminæ are not closely applied, and least in the dorsal regions, and is most marked at the base of the knuckle. In cases of long standing there may be atrophy from vertical pressure and, possibly owing to trophic changes, diminution in the length of the laminæ and spinous processes.

The calibre of the bony canal is rarely, and even then only slightly, diminished. Paraplegia may result from pressure of an abscess backward into the canal, inflammatory thickening or edema behind the dura, pachymeningitis, pressure by débris or by a sequestrum. The part played by the sharp bend is not proved. Laminectomy is generally useless, while the drainage of an abscess spontaneously or by a costa-transversectomy may relieve a paraplegia. A forcible reduction may either increase or relieve a paraplegia.

For repair, arrest of progress and absorption of residue are essentials. The production of new bone is insignificant usually, and thus differs from the conditions in a fracture. New bone practically never fills up a cavity. Bony union occurs only in areas of abnormal pressure and follows no regular laws, except that it usually precedes healing, begins in the posterior area, and is but slight and irregular anteriorly as a rule. New bone may be formed from the periosteum anteriorly and may unite the bodies at the anterior angle, bridge over a cavity or form along a sinus. Apparently mixed infection through a sinus aids bone formation, and may thus aid consolidation and the arrest of the disease. Anchylosis between the bodies is more fibrous than osseous and amid the partially fused masses are usually small foci of dsease.

CARLOT'S METHOD OF REDUCTION OF DEFORMITY IN POTT'S DISEASE.

Carlot [23] reports the case of a girl three years of age who died of scarlet fever five months after the reduction. There was an abscess found at autopsy, extending backward and forward, penetrating the pericardium. There was no bone retraction at the point of deformity. He is not in favor of Carlot's attempt at union of the spinous processes after cutting away the prominent spines. He is of the opinion that Carlot's more favorable results than those obtained by other surgeons may be due to over-violence on the part of the latter.

THE ANATOMY OF CONGENITAL DISLOCATION OF THE HIP.

Hinsberg [24] describes the anatomical appearances in a case of congenital dislocation of the hip in a woman seventy years of age. The dislocation was double, and the woman in life had the characteristic gait. The thighs were adducted, and the spine presented marked lordosis. The patient was active as a child, but in the last years of her life she was confined to her bed. The muscular system showed characteristic changes. The gluteus medius was weak, pale, and fattily degenerated in its greater portion, but the anterior portion was fairly well developed. The gluteus minimus was pale and atrophic; the curve of the pyriform muscle horizontal, and in this muscle, as well as in the obturator internus, the contractile tissue was small, while the tendinous portion was well developed. The gemelli were more muscular; the obturator externus and quadratus femoris were well developed. The iliac psoas muscle showed peculiar changes. The internal iliac was reduced to a small number of muscular fibres not sufficient to cover the iliac bone; the psoas, however, presented a certain number of not very strong muscular bands. The alterations in the shape of the pelvis were not as great as would be supposed, the diameters being practically normal. The plane of the pelvis was altered to such a degree that it was vertical, the symphysis pubis being horizontal. The ends of the femora were greatly changed, and were not the same on both sides; on the right the head had almost entirely disappeared; the neck was short and not easily distinguishable. The trochanter was well developed. On the left the trochanter major was weaker, and the head and the neck were the same as on the right but with more marked alterations. The tip of the trochanter major was somewhat drawn inward. The alterations in the capsule were very marked, to such an extent that the capsule had become thickened and the part which lay between the head of the femur and the acetabulum had been transformed into a thick band which surrounded its upper portion, the top of the femur being attached between the neck and the greater trochanter. The capsule was universally thickened, and the ligamentum teres was absent. The capsule had been transformed into a strong ligament surrounding the trunk to the neck of the femur. A false capsule had been formed about the head and the neck, or more properly speaking, a space covered by tissues from the gluteus medius and minimus. There was no trace of any socket. The bony structure of the femur was altered in such a way that the osseous fibres which normally pass to the head, strengthening this portion of the bone, were abnormally developed on the direction of the trochanter, with an increase of spongy bone in the direction of the head.

THE BLOODLESS METHOD OF TREATMENT OF CONGENITAL DISLOCATION OF THE HIP.

M. Kirmisson [25] reviews the articles of Koelliker [26] and Lorenz.[27] He agrees with Koelliker that the method usually does not really reduce the dislocation, but simply transposes the femoral head into a position near the acetabulum, securing thus a joint functionally more useful. Koelliker thus obtained two cures, 45 transpositions, and 11 failures. Kirmisson reiterates the views expressed in his "Traité des Maladies Chirurgicales d'Origine Congenitale." He admits that the functional result may be improved by the attempt at a bloodless reduction, but does not agree with Lorenz that a true reduction occurs. The operation is, except in rare cases, palliative only. Lorenz's own dissections show that a true reduction is usually impossible.

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

MALCOLM STORER, M.D., SECRETARY.

Meeting of December 19, 1899, the President, Dr. A. Worcester, in the chair.

Dr. C. M. Green showed a

FIBROID TUMOR OF THE UTERUS APPARENTLY IN A STATE OF INCIPIENT MALIGNANT DEGENERATION.

Dr. E. C. Dudley, of Chicago, read by invitation a paper entitled

STRICTURE OF THE URETER A POSSIBLE RESULT OF LACERATION OF THE CERVIX UTERI, AND URETEROVAGINAL FISTULA A RESULT OF TRACHELORRHAPHY.[1]

Dr. Edward Reynolds: This paper is one that opens up fields of thought. The idea is a new one. I agree with the reader that the only way in which the ureter could have been injured was that it was drawn into reach by cicatricial contraction. Ordinarily it is too far off to be reached by any stitch that would be likely to be put into the cervix. I am inclined to think that in the reader's case the bougie was quite as likely stopped by the cicatrix as by the stitch. I have seen several cases in which the ureter was very close to the cervix indeed, though I never happened to notice whether in those cases the cervix was especially badly torn. I have been struck by the ingenuity displayed by Dr. Dudley in closing the fistula. The question however arises in my mind whether there might not be some danger in leaving so patulous an orifice to the ureter, in view of possible ascending infection. The only time I have had to build an orifice to a ureter was in a case in which in removing papillary growths in the bladder I was forced to remove the ostium of the ureter, and had to stitch its edge in such a manner as to bring the pout-

[1] See page 215 of the Journal.

ing mouth of the cut ureter into the bladder. Cystoscopic examination a few weeks later showed an apparently normal orifice. The orifice of the ureter is normally somewhat smaller than its tube; only an 8 or 9 French bougie will pass, while the ureter above will take a 15.

Dr. M. H. Richardson: Looking at the matter from an anatomical point of view, the ureters have much the same relation to the cervix as the common carotids have to the trachea, and are correspondingly liable to be injured. Traumatic lesions of the ureter should, however, be avoided by selecting methods of operation which permit you to see just what you are doing; there is no need of putting in a catheter to see where the ureter is; it is perfectly easy to find it in the course of an abdominal hysterectomy, for instance, by a little dissection. Tie and clamp only what you recognize and you will not injure the ureter. Personally I have never happened to see a wounded ureter. Every year I demonstrate to the students the various methods of dealing with them, some of which, as, for instance, the insertion of a wounded ureter into the bladder, are very beautiful procedures. While *a priori*, the possibility of a tear in the ureter coming from a laceration of the cervix would seem rather remote, further consideration does not make it seem so entirely impossible. I do not, however, think that the ureter could be torn as long as it is in easily distensible tissues, but if it is imbedded in a mass of inflammatory exudate such a tear might arise. I do not see just how it could be included in a stitch through the cervix. It would seem to me that in Dr. Dudley's case the suture passed to control the bleeding was far more likely the cause.

Dr. Engelmann: The important lesson to be deduced from a case like this is of course the effect of laceration upon the position of the ureter. I have seen the ureters displaced by pressure of tumors and also cases in which I thought lacerations of the cervix were the cause. I should think cicatricial drawing down might be a real condition, and of course pain resulting from that would not be helped in any way by restoring the cervix.

Dr. J. G. Blake: In looking up this subject the only reference I could find was that Emmet speaks of displacement of the ureter as being possibly caused by inflammatory changes. This case is certainly unique, and we should thank Dr. Dudley for having called our attention to a possible explanation of our failure to relieve symptoms in certain cases of restoration of the cervix.

Dr. Dudley: Undoubtedly stricture of the ureter may arise from traumatism, due to pressure by the child or from cicatricial contraction or from other causes which have nothing to do with parturition. I think we have little to fear from the suggestion of Dr. Reynolds that the ureter may remain too patulous and that it may therefore furnish a ready avenue for the passage of infection toward the kidney. I would more fear too much contraction at the ureterovesical orifice. In this case I was glad enough to have succeeded to re-establishment of the current of urine into the bladder. I really gave little thought to the possibility of an excessively large ureteral orifice. In this case there has been since the operation no indication of an ascending infection. Perhaps nature would establish a valve-like protection. As already stated, the lumen of the ureter is narrower at the vesical orifice than higher up. In this respect the ureter is like other ducts. The structures, however, surrounding the orifice are so elastic that they would readily stretch to the diameter of an instrument that would be large enough to measure the calibre of the ureter above. The chief purpose served by the operation on the cervix in this case was merely to disclose the stricture. I would especially emphasize the fact that there may be other cases like this one in which the operation of trachelorrhaphy would not fulfil the essential indication.

Recent Literature.

Hermann Ludwig Ferdinand von Helmholtz. By John Gray McKendrick, M.D., LL.D., F.R.SS.L. and E., Professor of Physiology in the University of Glasgow, and Fellow of the Royal College of Physicians of Edinburgh. Pp. 299. New York: Longmans, Green & Co. 1899.

This compact and attractively bound volume is one of a series on the masters of medicine, several of which have already appeared. The book is a summary of the life and scientific achievement of one of the greatest men of the nineteenth century, a man whose influence has been felt in many fields of research. Helmholtz's private life was of the simplest character and uneventful in other respects than scientific endeavor. He was from his earliest years a profound and absorbed student, and found little time or opportunity for travel. Beyond visits to England and one late in life to America, his life was passed in the studious atmosphere of German universities.

The writer of this comprehensive biography has done well in describing in outline the various scientific achievements of Helmholtz, even at the risk of detracting somewhat from the popular interest in his pages. This difficult task has been successfully accomplished, and we have in the sketch presented us a highly appreciative account, reduced to the smallest possible space, of the great scientist. The book is interesting throughout, in spite of many necessary technical details. A somewhat incomplete index and a bibliography, chiefly of the writings of Helmholtz, concludes the volume.

Bacteriology in Medicine and Surgery. By William Hallock Park, M.D., Associate Professor of Bacteriology and Hygiene, University and Bellevue Hospital Medical College, etc. New York and Philadelphia: Lea Brothers & Co.

This book is designed to be a text-book of bacteriology for students and also to be of use to physicians and health officers. The technical side of bacteriology is not extensively treated, for the book is not regarded as a laboratory manual. Special attention has been given to such subjects as the chemical changes produced by bacteria, infection, immunity, serum therapy and the diagnostic value of bacteriological cultures. Considerable space is alloted to the consideration of disinfectants and to other subjects such as interest officers of health boards. The book as a whole is by no means a thorough one, but it will probably be of some use to the class of readers to whom it is addressed.

The following errors or special defects have met our notice: On page 28 Hansen's name is misspelled.

On page 30 Canon is erroneously credited with a part in the discovery of the bacillus of influenza. The gonococcus is stated to be frequently capable of growth in the peritoneal cavity. This statement gives the impression that the organism is frequently found in that situation. As a matter of fact, cases of peritonitis in which the gonococcus has been demonstrated beyond question are extremely few. Its supposed frequent invasion of the peritoneum is largely the result of speculation and inference. The section dealing with the correction of the reaction of culture media by titration is very obscure and needs revision. The statement that smegma bacilli have never been identified in other parts of the body except in the neighborhood of the genitals is open to question, inasmuch as they are reported to have been observed in cases of gangrene of the lung. On page 378 what is apparently a misprint reads that two cubic centimetres of culture media are sufficient for each tube.

The book contains numerous reproductions of new photomicrographs of bacteria. These are for the most part disappointing, and are inferior to the well-known reproductions from Fränkel and Pfeiffer's "Photographic Atlas of Bacteria."

The book is attractively printed and bound, and contains 680 odd pages, with an index.

Refraction, and How to Refract. By JAMES THORINGTON, A.M., M.D. Pp. 301. Philadelphia: P. Blakiston's Son & Co. 1900.

This handy octavo volume is the result of a series of lectures delivered by Dr. Thorington to former pupils. The subject is treated systematically in twelve chapters that contain two hundred or more illustrations, some of them being in colors. Although this little book was intended for students' use, the practical ophthalmologist may find profit in its perusal. The sections allotted to retinoscopy and muscles are to be commended, and the chapter which explains the adjusting of frames, although more directly related to the mechanical part of the art, will certainly interest even the casual reader. There is a decided preference given to atropine as a cycloplegic over homatropine and some of the other more quickly acting and more ephemeral remedies. The many formulæ which are frequently brought into the text serve very well to elucidate the problems therein presented. There is a very good index, and the presswork is excellent.

Crockett's Gynecology. A Pocket Text-Book of Diseases of Women. By MONTGOMERY A. CROCKETT, A.B., M.D., Adjunct Professor of Obstetrics and Clinical Gynecology, Medical Department of the University of Buffalo, N. Y. Philadelphia and New York: Lea Brothers & Co. 1900.

This book has been handsomely put out by the publishers. The binding is attractive, the paper good, the type and illustrations neat. The latter, which are not profusely used, are mostly copied from recent text-books, notably Dudley's. The author has undertaken the very difficult task of condensing the subject matter of the larger text-books into 350 small pages, making but little other alteration of the material in the process, and has performed his task well. The book seems to be an excellent specimen of this type of work.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MARCH 1, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

SANATORIA FOR TUBERCULOSIS, AND PROPHYLAXIS.

No one subject is of more practical and absorbing interest, alike to the physician and sanitarian, than that of tuberculosis. The reproach so often raised against us that we are making no practical advance in the treatment of many diseases does not apply here. Tuberculosis is being treated rationally and successfully, and a beginning has certainly been made toward its ultimate extermination. This has been brought about, first, by the recognition of the underlying specific cause of the disease, and secondly, by painstaking care in its treatment when actually developed. Legislatures have come to recognize the necessity of hospitals devoted to the care of tuberculous patients, and we may look forward to the rapid increase of such institutions in the future. With this progress, rightly regarded as an achievement of great magnitude, we must not forget that, after all, the causes of tuberculosis lie far behind the bacteria, in those conditions which induce susceptibility, whether through hereditary transmission or, probably even more important, through unhygienic modes of life. We certainly need hospitals for consumptives, and a great many of them, but what we need still more is the extermination of the breeding places of tuberculosis, which exist in every one of our large cities, and are a constant menace to health. The ultimate problem is not to be solved by the hospital, but by the prevention of the conditions which make the hospital necessary. The housing of the poor becomes, therefore, of paramount importance, for it is in the tenement districts that we may look for the centres of disease. The recent agitation in New York regarding tenement house construction, and the conferences held relating to these public questions, will, no doubt, strike at the root of the evil. At the recently held tenement house exhibition, a model representing the most populous block in New York City was shown, where 4,000 persons live. Of the 2,639 rooms in the houses, only 1,198 have windows facing the outer air, and there is not a bathtub in the block.

This is undoubtedly a type of the place where reform should begin if disease is not to gain a firm foothold.

In a short paper on "Sanatoria for Consumptives" in the *St. Louis Courier of Medicine*, January, 1900, Dr. Beverley Robinson, of New York, makes certain vigorous statements which are well worth our attention. He says, in part, speaking of tuberculosis:

"Take the poor in our large cities and towns; are they not the ones most frequently affected, and for whose welfare we should be most concerned, since they are in much larger number? Let our legislatures, then, see to it that in the tenements the air supply is sufficient and good, let sunlight penetrate dark, ill-smelling rooms, let cleanliness be obligatory. Enforce proper oversight of food and water supply, and soon, very soon, tuberculosis will diminish very greatly. . . . Now, then, should we build sanatoria throughout our land, equip them with every modern improvement, make a large outlay of private or public funds, only after a shorter or longer period of rest, nursing, medical care, to send back these same persons either cured, improved, stationary or worse, to conditions and surroundings which are the source and origin, in my judgment, far more of the widespread pest of humanity than the *microbe*, whose inoffensiveness is demonstrable when the causes which breed it and make it important cease to exist? The microbic theory of disease is very well as a working basis for our sanitary corps, for our practitioners and even our surgeons, because everywhere it is recognized it makes *purity* through *cleanliness*. But when we lose sight of other great and important facts of medicine — old, and older than our civilization — it dwarfs the intelligence and leads to sad departures from common sense and logical deductions."

This is wholesome advice. It means no disparagement of the hospital for tuberculous patients, which we shall probably always continue to need, but it forces upon us the conviction, which we are sometimes inclined to forget, that natural means of combating disease are better than artificial ones, and that in fresh air and sunlight and cleanliness we have the strongest allies against disease in general, and particularly against tuberculosis.

SOME ANTIVIVISECTION "ARGUMENTS."

A LETTER of more than usual effrontery has appeared in a recent issue of a much read Boston evening paper, from the pen of J. M. Greene, Treasurer New England Antivivisection Society. After easily disposing of certain arguments raised by Mr. Olmsted's recent letter in the same newspaper, on the ground of Mr. Olmsted's ignorance of the subject, he proceeds to expose a degree of ignorance on his own part which is quite inconceivable, and which we are convinced can be of no benefit even to an unreasonable cause. We quote in part:

"Now, I beg to suggest that if you possessed that acquaintance with the subject which you now disclaim, you would not attach so much importance to the experiments you mention. You would then know that they are carried on by specialists as a commercial enterprise throughout the world, and the 'serum' products 'boomed' and sold at an enormous price without the slightest regard to their actual value. You would know that such experiments on consumption by Professor Koch were an absolute failure, and that there is no sign at present of any improvement in that direction. You would know that the 'plague serum' of Haffkine in the East was a fiasco, that the treatment was in many cases attended by an increase of the disease, and that the disease is now spreading. You would remember that such experiments on yellow fever (during which human beings in Montevideo, S. A., were deliberately poisoned to death by Professor Sanarelli, inasmuch as experiments on the lower animals were found to be inadequate) have been empty of results, the 'bacillus' even of the disease not yet being secured. You would be aware of the fact that Behring's diphtheria antitoxin, so much vaunted and advertised, is as collossal a fraud as has yet been imposed upon a suffering public; that the only virtue in said antitoxin resides in the carbolic acid in which it is preserved; that carbolic acid in water alone produces better results without the injurious effects upon the vital organs often caused by the serum."

And why should we be asked to bow down to the authority of Mr. Herbert Spencer in a matter relating to the serum treatment of disease? These "arguments" are beyond our comprehension.

MEDICAL NOTES.

ANOTHER EXTRAORDINARY LAW SUIT. — A decision of unusual interest has been handed down from the Illinois State Supreme Court. The suit was against a Chicago hospital, brought by an infant, in which it was sought to recover damages to the extent of $50,000 for injuries sustained by the plaintiff before his birth. Shortly before the birth of the child the mother was in St. Luke's Hospital, and while being transferred from one floor to another her leg was caught in the elevator and crushed. When her child was born his left foot, left side and left leg were paralyzed and deformed. The mother brought suit for the child. A general demurrer to the declaration was sustained by the Supreme Court on the ground that at the time of the accident the child could not be credited as a separate being, capable of sustaining an action independent of the mother. "If an action can be maintained," the Court says, "it necessarily follows that an infant may maintain an action against its own mother for prenatal injuries." In such a case it would likewise appear necessary to establish beyond question the fact that the injury to the child was actually due to the accident to the mother, and was not a coincidence merely. In this instance the latter hypothesis would appear the more reasonable.

REVIVAL OF AN "INDEX MEDICUS." — It is announced that beginning with February 15, 1900, a publication devoted to an International Bibliography of the Medical Sciences will appear monthly, on the general plan of the now discontinued American *Index Medicus*. The undertaking is under the auspices of the Institut de Bibliographie of Paris. Each number will comprise about 80 pages, appearing the fifteenth of each month, and containing an international bibliography of the preceding month. Letters, communications, books, etc., should be addressed *franco* to M. le Dr. Marcel Baudouin, editor-in-chief, at the Institut de Bibliographie, 93, Boulevard Saint Germain, Paris.

FAMINE AND PLAGUE IN INDIA.— It is reported that over 61,000,000 persons in India are affected by the prevailing famine, while only about 4,000,000 are receiving relief. In spite of these facts the death-rate through the affected district of 550,000 square miles is decreasing. The Indian Government has issued a resolution approving Professor Haffkine's anti-plague inoculation, and the viceroy, Lord Curzon, is advocating its use.

A STATUE OF HAHNEMANN. — A bill has recently passed Congress appropriating $4,000 for the pedestal for a statue of Hahnemann, to be erected in Washington by the homeopathic physicians of the United States, and authorizing the selection of a site for this statue on a public reservation.

PLAGUE REPORTED AT HILO.— The War Department has received news reporting the presence of plague at Hilo. This is the only Hawaiian port at which American vessels have stopped since plague broke out at Honolulu.

FAMILY PHYSICIANS IN MONTANA. — Queer family physicians they have in Montana. The testimony in the senatorial bribery case indicates that some of them spell themselves heelers.— *Herald.*

AGED ONE HUNDRED AND FOUR. — Rev. Booker Fox, of Ottumwa, Iowa, an evangelist, died recently, aged one hundred and four. He was born at Nashville, Tenn., in 1796.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the eight days ending at noon, February 28, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 106, scarlatina 52, measles 58, typhoid fever 9.

AID FOR THE WEST END NURSERY.— The result of a recent fair in aid of the West End Nursery and Infants' Hospital resulted in the receipt of $5,450.

A BEQUEST TO A HOSPITAL. — Through the will of the late Benjamin Sweetser the New England Hospital for Women and Children receives $2,000.

DECREASE OF DISEASE IN BOSTON.— Last week the health of the city was better than it had been for a long time; encouraging health reports were received from all parts of the State of Massachusetts. There was a large decrease in the number of cases of diphtheria and scarlet fever, and there is ample room at the City Hospital for the proper isolation of all cases which come under the observation of the Board of Health. The number of deaths reported for the week is 227 as against 255 the corresponding week last year, showing a decrease of 28 deaths, and making the death-rate for the week 21.3. The number of cases and deaths from infectious diseases is as follows: Diphtheria, 76 cases, 9 deaths; scarlatina, 43 cases, 5 deaths; typhoid fever, 3 cases, no deaths; measles, 47 cases, 1 death. The deaths from consumption were 27; pneumonia, 42, and heart disease, 27.

NEW YORK.

A QUESTION OF JURISDICTION. — The authorities of New York having claimed the right, under the charter of the city, to inspect the buildings of the State hospitals for the insane located within the city limits and to direct the manner of construction of new buildings for such hospitals, the Attorney-General has now decided that the city has no such jurisdiction. The opinion was requested by State Architect Heins, in view of demands made by the City Police Department to inspect and license boilers to be operated at the Manhattan State Hospital on Ward's Island, and by the Buildings Department of the city to supervise the erection of an ice-house at the Long Island State Hospital at Flatbush. Attorney-General Davies, in his opinion, denies that there is anything in any provision of the charter conferring such jurisdiction, and claims that the right of the State to manage and control the State hospitals, free from interference or supervision of the city of New York, is an attribute of sovereignty which has not been relinquished or in the slightest degree bestowed upon the city, so far as pertains to this matter. In support of this opinion he cites the fact that under an act of 1896 the State specially permitted peace officers to exercise their authority upon the hospital grounds and premises, thus in effect declaring the principle that local jurisdiction over lands owned or under the control of the State are excluded from municipal supervision, unless a special permit or privilege therefor is provided by the State.

ANNUAL REPORT, STATE BOARD CHARITIES.— The State Board of Charities submitted its annual report to the Legislature on February 19th. Generally speaking, the board finds that the conditions among the dependent poor have improved during the year. The Kings County Almshouse and Hospital, in Brooklyn, are condemned as inadequate and in bad sanitary condition. The establishment of a State hospital and of municipal hospitals for consumptives is recommended. The present Commissioner of the Department of Charities in New York City, and the efficiency of the institutions under his control, receive high commendation. There is also warm praise for the Craig Colony for Epileptics, where additional accommodations are asked for. In regard to the law enacted last year for the prevention of the abuse of

medical charity, the report says: "The operation of the law as observed by the department has already had the effect to abolish that misnomer, the private dispensary. It had long been the custom for physicians practising among the poor, especially in the Borough of Manhattan, New York City, to conduct their East-side offices under the name of this or that dispensary. The law, however, makes clear the intention to limit the use of the word dispensary or its equivalent to the operation of a charitable enterprise. A second result is the withdrawal from the dispensaries of that class of persons who, able to pay for medical treatment, prefer to do so rather than to sign application cards.

The Tenement House Question. — The Tenement House Exhibition closed on February 24th, and on every evening during its last week there were conferences and public discussions in the rooms where it was held. The series was opened by Lawrence Veiller, Secretary of the Tenement House Committee of the Charity Organization Society, who made an address on "The Exhibition and its Meaning." The exhibition, he said, had been prepared for the purpose of stimulating interest in the tenement house problem by placing before the public in concrete form a clear and comprehensive statement of existing conditions, so that intelligent action might be taken to remedy them. The solution of the problem, he thought, lay along three distinct lines: (1) Through the enactment of wise restrictive legislation; (2) through the building of model tenement houses as commercial enterprises; (3) through the improvement and proper management of existing old tenements and the condemnation of buildings unfit for habitation.

Opposition to a Small-pox Hospital. — Two cases of small-pox having appeared in New Rochelle, Westchester County, the Board of Health promptly bought an acre of land a short distance outside of the city and proceeded to erect a frame isolation hospital. The neighboring farmers, however, were so strongly opposed to having the pest-house in their vicinity, that they forced the carpenters who were engaged on it to desist from work, and it was not until the aid of the police department had been secured that the building could be completed.

Quadruplets. — The wife of a German grocer living on East Fourth Street recently had four children at a birth, three of whom were males. All four were born alive, but they were quite small, weighing only about two pounds each, and only survived for a few hours. The mother, who on a previous occasion gave birth to twins, is reported as doing well.

ARMY NOTES.

Plague. — A report has recently been received from Major Taylor, chief surgeon in the Hawaiian Islands, concerning the prevalence of bubonic plague in Honolulu. Up to January 22d there had been a total of 46 cases, with 40 deaths. The whole town has been districted and each house is inspected twice daily and the condition of the inmates noted. During the burning of a portion of Chinatown, the flames got beyond control and destroyed nearly all the district, rendering about 4,000 Chinese and natives homeless. It is apprehended, while the destruction of the native quarter was providential, that during the confusion incident to the conflagration, much household property was removed to widely scattered points, and that new foci of infection have thus been created. While no cases of plague have occurred among the United States troops at Honolulu, a temporary hospital has been established in readiness for a possible outbreak, and a detention camp for suspects has been provided. The hospital is excellently located, is abundantly equipped for any emergency and has an ample *personnel* of nurses and hospital-corps men.

Vital Statistics of Havana for 1899. — A report on the vital statistics of Havana for the year 1899 shows that in an estimated population of 220,000, there were 8,153 deaths from all causes; 1,163 of these being due to enteritis and 1,307 to tuberculosis. Yellow fever occupies a relatively low position on the list, only 103 deaths having resulted from this disease. Leprosy was the cause of 11 deaths. The number of contagious and infectious diseases of all kinds reported amounted to 6,442; of which 284 were yellow fever. The births during the year numbered 4,181, of which 1,516 were illegitimate.

Insane Soldiers. — Newspaper statements having been made to the effect that about 500 soldiers serving in and around Manila had become insane and had been returned to the United States in this condition, an official investigation has been made as to the truth of these statements. It has been found that since the outbreak of the war with Spain, a total of 223 men have been committed to the Government Hospital for the Insane by the Secretary of War, of which 129 have since been discharged. Of the total number of 223, only 37 men served in the Philippines, and of these 11 have been discharged as cured.

Increase in Army Medical Corps. — It is understood that the bill proposed by Surgeon-General Sternberg for a much needed increase in the Army Medical Corps has received the full support of the Secretary of War, and will soon come up for Congressional action.

Miscellany.

THE TENEMENT HOUSE AND TUBERCULOSIS.

At one of the conferences at the recent Tenement House Exhibition in New York, Dr. S. H. Knopf read a paper on "The Tenements and Tuberculosis." The disease, he said, is an endemic of the tenement house. The cases are far more numerous than the reports to the Board of Health show, and the tuberculous invalid who is up and supporting his family is perhaps the greatest danger to the community. So long as the

present laws governing the building of tenements exist, so long will special hospitals continue to be daily recipients of cases created anew. While the establishment of sanatoria will be of great service, the most important factor in solving the tuberculosis problem will be the proper housing of the poor. With modern tenement houses, under adequate management, the danger from tuberculosis, as from other infectious diseases, would be reduced to a minimum.

At the last conference Jacob Riis, author of "How the Other Half Lives," was the principal speaker. In the course of his remarks he said: "We are not struggling with a problem peculiar to New York. The battle is an old one, and exists in every country. Human greed is still potent for harm, and the tenement house evil is a greater menace to a republic than to a monarchy. I thank God that we are at last talking about souls in tenement houses, and not about so many soulless creatures that only exist to pay rent. In 1857 the people first awoke to the fact that poorly ventilated tenements and bad plumbing caused disease. The committee sent down by the Legislature to make an investigation found that the infant mortality was something frightful to think of, and it reported that the condition of the tenements was chiefly responsible for the trouble, and that poverty should not be compelled to commit suicide by living in houses put up by conscienceless builders. Ten years later another legislative committee found that of 18,582 tenements in New York, 52 per cent. were dangerous to the lives of the persons residing in them and detrimental to the health of the entire city. Moreover, in 32 per cent. of this number the trouble arose purely from overcrowding and neglect of ordinary sanitary precautions by the landlord. Both of these committees laid down lines to overcome the evil. One of the suggestions was that tenements should be licensed to hold a certain number of persons and that the landlord should be held rigidly accountable for any excess of that number. There are now some 40,000 tenements, and if each of them had to pay a license fee of $2.00 a year, the sum realized would be sufficient to pay the entire expense of maintaining the sanitary police, which does nothing else but see that landlords obey the law. It is interesting that, whereas the committees came down to find out what was the matter with the people, they reported that the trouble was entirely with the tenements. The people were better than their houses. Our fight is for the American home. Without homes there is no family, no manhood, no patriotism. The way out of the difficulty is to arouse the public conscience and keep it aroused. The builder should be compelled to realize that he is his brother's keeper. He would not be allowed to murder his brother with a knife — he should not be permitted to murder him by cutting off his air and sunlight."

DETERMINATION OF SEX AT WILL.

THIS ever interesting question has a new expositor in Dr. J. Griffith Davis, who writes in the current number of the *New York Medical Journal* her theories and deductions. Her idea is based on observation and to a certain extent on experiment among the lower animals, which have left her with certain perfectly definite convictions. The whole matter, to her mind, rests upon the exact time, in relation to menstruation, that impregnation takes place, or as she much more euphemistically puts it, upon the date at which a "guest is invited." Guests invited from three days before to about eight days after the menstrual period are likely to be girls, whereas those invited from the tenth to the fifteenth days are almost sure to be boys.

The ninth day is a doubtful time, in which two guests may arrive — twins — or, if but one, that one may be of either sex, but usually having characteristic attributes of the other sex. The success of this plan in practice evidently demands a painstaking oversight of the sexual life of the parents, and much discriminating self-denial in offering hospitality to guests. Interesting as the facts may be, we see some slight difficulty in putting the plan into active operation among members of the human family.

Obituary.

W. H. H. HASTINGS, M.D.

DR. W. H. H. HASTINGS died suddenly in Boston, after a brief illness, February 16th. He was about sixty years of age, and graduated from the Harvard Medical School in the class of 1868. He was successful as a practitioner of medicine, had a good practice and his patients were much attached to him. It was, however, as Superintendent of the Boston Dispensary that he was best known. His life work was in connection with this old and most useful institution. He served as superintendent for twenty-four years, and his official relations to the Dispensary covered at least a quarter of its existence. Its present commodious home was erected under his supervision, and its departments and staff of medical attendants have been constantly and judiciously increased during his tenure of office. To-day the medical staff of the Boston Dispensary consists of not less than seventy members. Although appointments rested with the Board of Managers, the selection of candidates was largely in the hands of the superintendent, and this responsibility was almost invariably discharged by Dr. Hastings with excellent judgment and discretion. In the advice which he was called upon to give, and the general administration of his office, the balance was kept adjusted between the zealous enthusiasm of young professional men and the wholesome conservatism of a managing board, so that the sick poor profited by the best to be had both from the medical and business men of this community.

Dr. Hastings combined firmness with sweetness of character in just proportions. The work which he did in Boston will be no better done, whoever his successor may be.

Correspondence.

STREET PAVING IN BOSTON.

BOSTON, February 25, 1900.

MR. EDITOR: — At a meeting of the Medical Improvement Society, on February 19th, the evils of dusty streets were described, and the remedy proposed of asphalting the entire Back Bay district. A number of papers were read upon the irritating and inflammatory effects of dust, and an account given of its possibilities as a conveyor of infection.

It would have been interesting in this connection to have had some information as to whether during the past winter any marked increase of disease had been noticed among the classes most exposed to dust, such as the hackmen, postmen and outdoor laborers of the Back Bay. After the medical papers a gentleman who is, I believe, a

constructor of asphalt roadways read an essay on "Asphalt and its Merits as a Pavement." Two or three other gentlemen, who spoke as experts, seemed to favor asphalt.

Apparently there had been no arrangement made for a statement of the disadvantages of asphalt paving, or for the merits of any other kind of roadway. For instance, there is a company in Philadelphia which constructs brick pavements. There is a specimen of this on Arlington St., which certainly does not seem to have worn very well, yet it would have been desirable to have had a representative of the company to explain its claims for consideration. Presumably, he could have pointed out some of the disadvantages of asphalt. The brick pavement has certainly two merits, one that it affords some foothold for horses, and the other that it will bear any amount of water, which asphalt will not. Granting, however, that Beacon St., which has become a street for heavy traffic, and Marlborough St., which is somewhat in the same category, would be benefited by asphalt surfacing, it does not follow it would be necessary to carry this over the rest of the Back Bay. As far as the inhabitants of the above streets are concerned, they get very little dust from the south. When the wind is in that quarter it generally rains. Our great dust-storms are caused by the northwest winds.

There is a dusty area towards the west to which all our Back Bay streets lead, where the northwest wind has full play and will have until this region is built up. For Beacon St. and Marlborough St. dwellers to complain that they would get dust from Commonwealth Ave. finds its historic parallel in the accusation of the wolf against the lamb. The terrible heat in summer from a large district covered with asphalt, which would affect the comfort of the whole city, and its injurious effect upon the eyes are self-evident. It may also be mentioned that while asphalt diminishes the noise of wheels of heavy teams, it makes a ringing sound when struck by horses' shoes which is very annoying to many, and would to that extent be harmful to nervous invalids.

As regards Commonwealth Ave., for which I am principally concerned, it should continue a macadamized park road. Asphalt is, under certain conditions, which occur more frequently in the winter, very unsafe for travel, and there should be at least one road out of the city that could be used at all times. With proper care and proper watering, which it has not had, it could be made comfortably free from dust; and when we speak of proper care, this applies to all roadways. Asphalt must be kept scrupulously clean, else its quality as a non-absorbent renders it a menace to health instead of an advantage. Proper care may be promised and provided for, yet with the geographical position of our streets and the usual municipal manner of care-taking, it is more than probable that this cleanliness would prove to be an iridescent dream. I fear that this communication is reaching too great a length, but in view of what I have already stated, it seems to me that the Society did not approach the subject in exactly a judicial way. None of the above objections were put forth, presumably because every one had made up his mind beforehand. The writer, though not fully prepared, was strongly tempted to make some remarks, but when the opportunity came, the lateness of the hour and the unanimity of the audience determined him to simply utter a few words of protest against this sweeping scheme of asphalting the whole residential portion of the Back Bay.

Very truly yours,
S.

[The "two or three other gentlemen" referred to by the writer were: Dr. S. H. Durgin, Chairman of the Boston Board of Health, C. Frank Allen, Esq., Professor of Railroad Engineering in the Massachusetts Institute of Technology, and W. E. McClintock, Esq., Instructor in Highway Engineering in the Lawrence Scientific School of Harvard University, also connected with the Massachusetts Commission for State Highways.

As additional disinterested testimony we reproduce replies received in answer to a circular letter sent out by Dr. Henry O. Marcy in 1894.[1] They represent, purposely, several of our larger cities in widely varying latitudes with marked variations of climate:

CHIEF SANITARY INSPECTOR'S OFFICE,
ATLANTA, GA., July 23, 1894.

DEAR SIR: — Your letter of July 20th to hand, and in reply will state that I consider the "asphalt paving" the prettiest paving for your avenues in Boston; it is easily kept clean, is noiseless, and would give entire satisfaction. Any further information I will gladly furnish.

Very respectfully,
THOS. E. VEAL,
Chief Inspector.

CITY SURVEYOR'S OFFICE,
MONTREAL, CAN., July 23, 1894.

DEAR SIR: — I am in receipt of your letter of July 20th, asking me for my opinion as to the best pavement to be used for a residential street with light traffic thereon. I would certainly recommend Trinidad asphalt. We have had Trinidad asphalt laid by the Warren Scharff Co., of New York, and it has stood this climate for seven years with heavy traffic.

Yours truly,
P. W. ST. GEORGE,
City Surveyor.

OFFICE OF CITY ENGINEER,
SAVANNAH, GA., July 25, 1894.

DEAR SIR: — Your note of July 20th came to hand and contents noted. The city of Savannah has a great many streets paved with asphalt, and it gives entire satisfaction. The Warren Scharff Paving Co. has done most of our work. It stands heavy traffic as well as light.

I am yours respectfully,
JOHN FITZGERALD,
Superintendent of Streets.

DEPARTMNET OF PUBLIC WORKS,
CHICAGO, July 23, 1894.

DEAR SIR: — Your favor of July 20th, relative to asphalt pavement received. We have 16.65 miles of sheet asphalt streets in this city. This class of improvement when well laid has given general satisfaction on resident streets in this city. Dearborn Avenue, which was improved with asphalt eleven years ago, has just been repaired at an expense to the city of $570. It is now in as perfect condition as it was when originally completed.

Yours very truly,
JOHN MCCARTHY,
Superintendent of Streets.

DEPARTMENT OF PUBLIC WORKS, COMMISSIONER'S OFFICE,
No. 31 CHAMBERS STREET, NEW YORK, July 24, 1894.

DEAR SIR: — In answer to your inquiry of July 20th, regarding experience in this city with asphalt pavements, I beg to say that the experience of the last six years has shown good asphalt to be the very best pavement for residential streets and on streets used for pleasure driving, provided the grades are not too steep; that is, not to exceed 4 in 100. It has many advantages over macadam or stone, in being noiseless, impervious to liquid filth, easy to keep clean, and about one-fourth less expensive to maintain. We have now in this city fifty-five miles of asphalt pavement, nearly all in private residential and tenement house districts.

Very respectfully,
MICHAEL T. DALY,
Commissioner of Public Works.

STREET DEPARTMENT, STREET COMMISSIONER'S OFFICE,
ST. LOUIS, MO., July 24, 1894.

DEAR SIR: — Answering your favor of July 20th, would say we have a little over 100 miles of asphaltum streets in St. Louis, and they are giving entire satisfaction to the tax-payers. We have not confined the use of asphaltum streets to light traffic alone, as we have roadways here paved with that material over which from 5,000 to 7,000 vehicles pass daily with loads of from 1,000 to 10,000 pounds. Personally and officially I am in favor of asphalt for paving all classes of streets.

Very respectfully,
M. J. MURPHY,
Street Commissioner.

ED.]

Deaths reported 3,140; under five years of age 1,059; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping-cough, erysipelas, fevers and consumption) 652, acute lung diseases 705, consumption 335, diphtheria and croup 120, typhoid fever 41, measles 41, scarlet fever 41, diarrheal diseases 24, whooping-cough 21, erysipelas 15, cerebrospinal meningitis 14.

From scarlet fever New York 21, Boston 12, Philadelphia 3, Baltimore 2, Pittsburg, Washington and Malden 1 each. From diarrheal diseases New York 12, Philadelphia and Baltimore 3 each, Pittsburg and Charleston 2 each, Boston and Salem 1 each. From whooping-cough New York 13, Baltimore 2, Philadelphia, Boston, Pittsburg, Washington, Charleston and Lawrence 1 each. From erysipelas New York 8, Pittsburg and Providence 2 each, Philadelphia, Boston and Baltimore 1 each. From cerebrospinal meningitis New York 10, Worcester 2, Boston and Baltimore 1 each.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING FEBRUARY 24, 1900.

R. WAGGENER, pharmacist, granted sick leave for four months.

J. R. MURPHY, assistant surgeon, appointed assistant surgeon.

KARL OHNESORG, assistant surgeon, ordered to temporary duty at the Naval Academy.

W. G FARWELL, medical director, commissioned medical director from January 22, 1900.

D. N. BERTOLETTE, medical inspector, commissioned medical inspector from January 22, 1900.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING FEBRUARY 22, 1900.

MEAD, F. W., surgeon. Granted leave of absence for seven days from February 20th. February 19, 1900.

CARTER, H. R., surgeon. To proceed to Havana, Cuba, and resume duties as quarantine officer. February 17, 1900.

GUITERAS, G. M., passed assistant surgeon. Upon being relieved by Surgeon H. R. CARTER, to proceed to Matanzas, Cuba, and resume duties as quarantine officer. February 17, 1900.

PERRY, J. C., passed assistant surgeon. Detailed as chief quarantine officer of the Philippine Islands, and quarantine officer at the port of Manila. January 18, 1900.

ROSENAU, M. J , passed assistant surgeon. Detailed to attend the meeting of the Medico-Legal Society at New York, N. Y., February 21st and 22d. February 19, 1900.

EDSON, E. R., assistant surgeon. Relieved from duty at the Reedy Island Quarantine Station, and directed to proceed to the Gulf Quarantine Station for duty and assignment to quarters. February 17, 1900.

SOCIETY NOTICE.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday, March 5th, at 8 o'clock.

Subject: "Some Advances in Medical Instruction."

Prof. Wm. T. Councilman: "The Course in Pathology at the Harvard Medical School."

Dr. Herbert L. Burrell: "The Case System in Surgery."

Dr. Arthur H. Wentworth: "Section Teaching."

Mr. W. B. Cannon: "The Case System."

ARTHUR K. STONE, M.D., *Secretary*, 657 Boylston Street.

THE ASSOCIATION OF MILITARY SURGEONS OF THE UNITED STATES.

THE SANDER PRIZE.

Rules for competition for the Gold Medal of the value of $100, dedicated by Mr. Enno Sander, of St. Louis, for the best paper on Military Surgery, presented at the Annual Meeting of the Association of Military Surgeons of the United States.

1. Competition to be open to all members of the Association.

2. Each competitor shall send three copies of his essay, in a sealed envelope, to the Secretary, Lieut.-Col. Chas. Adams, Central Music Hall, Chicago, Ill., on or before April 15, 1900. The essay must be strictly anonymous, but the author shall adopt some *nom de plume* and sign the same to the essay, followed by a figure corresponding with the number of pages of the manuscript. A sealed envelope bearing the *nom de plume* on the outside, and enclosing full name and address shall accompany the essay. This envelope to be opened in the meeting of the Association after the decision of the Committee on the Prize Essay has been received.

3. The Committee will designate the essay worthy of the prize, and also in their order of merit those deserving of honorable mention. Should the Committee deem proper, it may recommend neither prize nor honorable mention.

4. The successful paper shall be published in the *Transactions* of the Association.

COL. N. SENN, Surgeon-General, I. N. G.
MAJ. A. C. GIRARD, Surgeon, U. S. A.
CAPT. GEO. W. WOODS, Medical Director, U. S. N.
Committee.

RECENT DEATHS.

EDWARD AUGUSTUS PERKINS, M.D., M.M.S.S., died in Boston, February 20, 1900, aged seventy-two years.

GEORGE MORRILL FRENCH, M.D., M.M.S.S., of Malden, died at Suncook, N. H., February 23, 1900, aged forty-five years. Dr. French was born at Sandown, N. H., and received his medical education at the Harvard Medical School. He had practised medicine about fifteen years at Malden. He is survived by a widow, a son and a daughter.

EDWARD F. MARTIN, M.D., who for twenty years was connected with the New York City Board of Health and who had recently been appointed Chief Food Inspector, died at his home at Elmshurst, Long Island, on February 24th, from Bright's disease. He was forty-four years of age.

JOSEPH M. CREAMER, M.D., of Brooklyn, New York, died on February 23d at the age of forty-six. In 1892 he was elected coroner, and served for three years. He was a son of Dr. Joseph F. Creamer, a well-known surgeon who died about six years ago.

SAMUEL R. FORMAN, M.D., of Jersey City, N. J., died on February 19th, from Bright's disease. He was a graduate of Princeton University and of the College of Physicians and Surgeons, New York, and was sixty-four years old.

BOOKS AND PAMPHLETS RECEIVED.

The Surgical Aspects of the Modern Small-Bore Projectile. By August Schachner, M.D., Louisville, Ky. Reprint. 1900.

Proceedings of the American Medico-Psychological Association at the Fifty-fifth Annual Meeting, held in New York, May 23-26, 1899.

Original Articles.

REMARKS ON THE INFLUENCE OF TECHNIQUE UPON THE RESULTS OF CLOSURE OF WOUNDS OF THE ABDOMINAL WALL.[1]

BY CHARLES P. NOBLE, M.D.,
Surgeon-in-Chief, Kensington Hospital for Women, Philadelphia.

It is my intention this evening to bring before you a number of points in the technique of the closure of wounds of the abdominal wall, and to report my own experience therewith as a contribution to what I hope may prove a valuable discussion upon these subjects.

There are a number of methods advocated for the closure of the wound in celiotomy cases. What may be called the classical method is that in which interrupted through-and-through sutures of non-absorbable suture material are employed. Silk, silver wire and silkworm gut have been advocated at various times. This method was universally employed by our predecessors, and probably to-day it is the method which has the greatest number of adherents. The advantages of the method consist in the rapidity with which the wound may be closed, and the comparative simplicity of the technique. The objections to the method are the relative frequency of hernia following its employment, and the relatively high percentage of wound infection and stitch-hole abscesses. I shall assume that these statements do not require statistical proof. Hernia is most frequent in the case of fat subjects and in those in which drainage has been employed — especially gauze drainage. The reasons for this are anatomical and self-evident. In thin subjects, when the suturing is carefully done, it is feasible to approximate with relative accuracy the component structures of the abdominal wall, restoring these structures approximately to their normal status. When drainage is employed, this is at once prevented at the site of the drainage opening. In fat subjects the mechanical difficulties of applying the sutures bring about the same result, and the component structures of the abdominal wall are not accurately approximated, and more especially the continuity of the aponeurosis of the transverse muscles is not restored. For this reason, in my judgment, this method of closing the abdominal wound should be reserved for the small class of cases in which drainage is necessary, and another limited class of cases in which, owing to the general condition of the patient, the saving of even a few minutes in the duration of the operation is of importance. It is my opinion that the explanation of the relative frequency of stitch-hole abscesses, when this method of closure is adopted, is that in order to close the abdominal wound with a single row of sutures, it is frequently necessary to tie these sutures under tension. In this way the circulation is interfered with, the vitality of the tissues is lowered, and any germs which may be present, whether the skin cocci or other, have a favorable field for action.

The foregoing considerations caused me to abandon through-and-through sutures in 1892, and since that time tier sutures have been employed as a routine method. The character of the suture material and the method of its employment have been changed several times. From May, 1892, until January, 1897, a row of interrupted silkworm-gut sutures was buried at the level of the aponeurosis, uniting the aponeurosis, recti muscles and peritoneum; and a second row of interrupted silkworm-gut sutures was employed to unite the skin and subcutaneous fat. Subsequent to January, 1897, the peritoneum and recti muscles were united with continuous catgut sutures, and the aponeurosis of the transverse muscles was united with a modified mattress suture (Fig. I) after the method detailed in the paper entitled "A New Method of Suturing the Abdominal Wound in Celiotomy."[2]

The results which were obtained by these methods were carefully recorded and reported to the American Gynecological Society at its meeting in Boston, in 1898.[3] The report embraced 472 cases, of which 10 suppurated, or two per cent. There were two post-operation hernias — one in the cases which suppurated, or 10 per cent., and one in the 462 cases in which primary union was obtained, or one-fifth of one per cent.

The results obtained by these methods both from the standpoint of the avoidance of hernia and from that of wound suppuration were eminently satisfactory. Silkworm gut as a buried permanent suture is undoubtedly an admirable suture material, provided it is aseptic and placed in an aseptic wound. This conclusion is not the result of a few experiments conducted over a limited period of time, but of ample experience extending over a number of years. I am quite aware that it has been controverted by other reporters, and that it is the current belief that perhaps 10 per cent. of buried silkworm-gut sutures will either immediately or remotely give rise to suppuration and require removal. In contradistinction to this received opinion, it can be stated, that of the thousands of sutures buried in the foregoing series of cases, in not a single case has a single suture ever required removal, provided the wound healed by primary union, and that the number of cases to which these buried sutures required removal was limited to 10 in which suppuration of the wound took place immediately after operation. I think it well to emphasize this point for future reference.

I would call attention to the following points as requisite to obtain satisfactory results with the use of silkworm gut as a buried suture: (1) That rigid asepsis be maintained in all the details of the operation, especially as to the hands of the operator and his assistants; (2) that light weight silkworm gut be employed; (3) that the sutures be tied without tension; (4) that the knot be made with three ties and then the ends cut off short, so that as small a foreign body shall be left for encapsulation as is feasible.

My confidence in the value of silkworm gut as a permanent suture is such, that although it is no longer employed in my routine abdominal work, it is still used to meet certain conditions. In all nephrorrhaphies three silkworm-gut sutures are used to fasten the kidney to the muscles of the loin. In all inguinal hernia operations at least one silkworm-gut mattress suture is used to close the internal ring of the inguinal canal; and in all femoral hernia operations the hernial opening under Poupart's ligament is closed with buried silkworm gut. In none of the hernia operations has

[1] Read before the Obstetrical Society of Boston, November 21, 1899.

[2] American Journal of Obstetrics, vol. xxxv, No. 4, 1897.

[3] Shall Absorbable or Non-absorbable Ligatures and Sutures be Employed, etc. Medical News, October 15, 1898; Transactions American Gynecological Society, 1898.

suppuration occurred, and in but a single nephrorrhaphy, of the date, March, 1896.

There are two legitimate objections which can be urged against the employment of silkworm gut as a buried permanent suture: (1) The use of interrupted sutures in closing wounds by the tier method requires a longer time than that of the continuous suture; (2) in the course of time pressure atrophy caused by the inclusion of tissue in the grasp of the suture may possibly lessen the strength of the abdominal wall. Neither of these objections is of a radical nature, but they had some effect in influencing me in at least temporarily abandoning the routine use of silkworm gut.

In May, 1898, I adopted the use of catgut exclusively for the closure of the abdominal wound, and since that date celiotomy wounds have been closed in the following manner: (1) The peritoneum is closed with fine cumol catgut (Fig. II); (2) the aponeurotic sheath of one rectus muscle (the right) is then separated from the muscle by blunt dissection, thus baring the under surface of the aponeurosis. The upper surface of the aponeurotic sheath of the left rectus muscle is then dissected clear of fat with a knife, with the object of suturing the under surface of the right aponeurosis upon the upper surface of the opposite aponeurosis. The suturing is then begun by passing the needle armed with medium chromicized catgut (sterilized by the cumol method) through the aponeurosis of the rectus muscle of the left side of the wound, and thereafter by continuous suture closing the rectus muscle until the opposite end of the wound is reached. The needle is then brought from below upward, through the aponeurosis upon the left side of the wound. The aponeurotic layer is then closed by passing the needle from below upwards through the aponeurosis upon the right side; then passing it through the aponeurosis of the left side as in the Lembert intestinal suture; and again from below upward through the aponeurosis of the right side, and so on till the end of the wound is reached, when a single knot completes the closure of the muscles and fascia (Fig. III).

The subcutaneous fat is then closed with a continuous catgut suture in one or more layers, using fine catgut. The skin is next closed by the intracuticular stitch with fine catgut.

In carrying out the technique scrupulous care is given to the following points: All bleeding vessels are controlled either by forci-pressure or catgut ligature; the wound is washed repeatedly with salt solution as layer after layer is closed, with the purpose of removing blood clots if present, and with the further object of washing away in part or in whole any germs which may have found lodgment in the wound; care is taken to avoid tension in drawing upon the sutures, so as not to interfere with the circulation. I was never able to appreciate the logic of those advocating the so-called dry method in dealing with wounds. By this method it always seemed to me that if the wound were infected, the more it was rubbed with dry gauze, the more thoroughly the infecting germs were rubbed into the tissues, and the greater the chances of subsequent inflammation and suppuration. The reverse of this is true when wounds are carefully and freely washed with salt solution.

FIG. I. Closure of the aponeurosis with the modified mattress suture.

Before giving the results which have been obtained by this method of closing the abdominal wound, it will be well to discuss a few points which are directly connected with these results. The abdominal wall is prepared by giving the patient a warm tub bath on the two days previous to the operation, care being taken to wash well the abdominal wall with soap and water.

When there are special reasons for extra cleansing, such as the recent use of mustard plasters or liniments, additional washings are employed and the

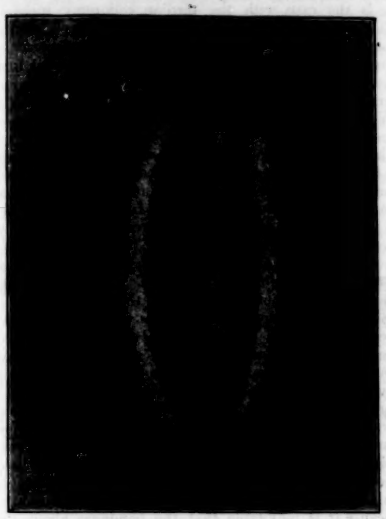

FIG. II. Showing (a) closure of the peritoneum with continuous catgut suture; (b) the borders of the (divided) rectus muscle; (c) the left aponeurosis freed from the layer of fat; the right aponeurosis separated from the rectus muscle and reflected.

scrubbing brush is used. On the morning of the operation, after a full bath, the abdomen is scrubbed with soap and water, the pubic hair is shaved, and the abdominal wall is then carefully cleansed with ether, alcohol and bichloride solution. A towel saturated in bichloride solution, 1–2,000, is applied over the region of operation and held in place by a bandage. When the patient is upon the operating table, the field of operation is again cleaned with ether, alcohol and bichloride solution. After the conclusion of the operation, the abdominal wall is again washed with bichloride solution and a number of layers of gauze rung out of bichloride solution, 1–2,000, is applied in its moist state over the wound; cotton is applied over this, and the dressing is held in place with sticking plaster, which dressing is not disturbed for a week. This method has been employed for ten years, and has given such uniformly satisfactory results that its details have never been varied. The adhesive plasters are used solely with the purpose of keeping the dressing in place and not to support the abdominal wound. When long adhesive plasters are used, they are very uncomfortable for the patient, especially if the abdomen becomes much distended with gas. The chief function of the adhesive plaster is to keep the wound covered with the dressing. I am satisfied that many wounds are infected and suppurate because of the neglect of this precaution. The wound is dressed for the first time from the sixth to the eighth day. The fine catgut employed to close the skin has usually been absorbed by this time, so that the dressing consists in picking off the knots and applying a fresh dressing.

One of the most important details in securing asepsis is the method employed in sterilizing the hands. It is universally agreed that in an absolute sense this is impossible, but with a proper technique this can be approximated. The permanganate of potash — oxalic-acid method of disinfection has been employed in the hospital of which I have charge for the past fourteen years, and constantly during the ten years of which I have had charge. The method in use is as follows: Operations are done in the morning, before either the operator or his assistants have soiled their hands. This is perhaps the most important individual point in the technique. Fifteen minutes is the time limit for scrubbing and disinfecting the hands. Green soap and a stiff brush are employed for about seven minutes, then the subungual spaces are cleaned with a sterilized wooden cleaner. The hands are again scrubbed with green soap and a brush, and are rinsed free from soap. The hands are then washed in alcohol, using gauze to scrub about the finger ends. To wash off the alcohol they are immersed in bichloride solution, 1–1,000, then in saturated oxalic-acid solution, and finally in saturated permanganate-of-potash solution. This process is then reversed. If the hands are put directly from the alcohol bath into the permanganate-of-potash solution, a reaction takes place, resulting in a sticky deposit upon the hands, which it is difficult to remove. The hands are now washed in

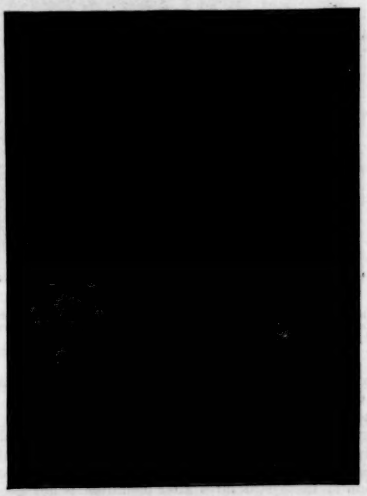

FIG. III. Showing (a) the wound in the rectus closed with continuous catgut suture; (b) closure of the aponeurosis by superimposing the right aponeurosis upon the left and suturing it with special form of continuous catgut suture.

sterilized lime water, and then in sterilized water. For the past year, after this has been done, rubber gloves, which have been boiled for fifteen minutes,

are put on. This method gives approximately perfect results, so far as wound infection is concerned.

The methods employed in the performance of the Alexander operation are very similar to those used in dealing with the ordinary celiotomy wound. March 2d of the current year I reported my experience with this operation before the Philadelphia Obstetrical Society.[4] At this time 62 operations had been performed. Since that date there have been six additional cases, making a total of 68. The teachings of Edebohls have influenced me largely in this operation, corrected of course by the results of my own experience. So far as their influence upon the healing of wounds is concerned, I think it only necessary to emphasize the following points: All hemorrhage is

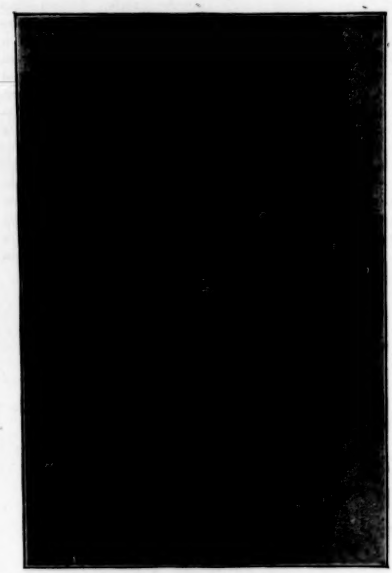

FIG. IV. Showing (a) suturing of the internal oblique and round ligament to Poupart's ligament; (b) the aponeurosis of the external oblique reflected and ready for suturing.

arrested either by forci-pressure or catgut ligature, so that there is no opportunity for the collection of blood in the wound after its closure. Special care is exercised not to draw the sutures too tight, especially those which embrace the ligamentous structures of the abdominal wall and the round ligament. The circulation in these structures after operation is not good, and tightly-placed sutures would necessarily result in strangulation and probably in suppuration.

It is not my purpose to go into details concerning the technique of Alexander's operation. Any one interested in this is referred to the above paper. In general I have followed the technique laid down by Edebohls, with the exception that instead of merely approximating the divided edges of the aponeurosis of the external oblique, that one layer of the aponeurosis is superimposed upon the other and there sutured, as is the case with the median celiotomy incision. The Edebohls technique after the drawing out of the round ligaments consists essentially in the performance of a Bassini hernia operation, the round ligaments being embraced in the sutures which unite the internal oblique muscles to Poupart's ligaments (Fig. IV). This, I believe, is the reason for the absence of post-operative hernias when this technique is employed. This sequel has been entirely absent in my own cases.

Suppuration has occurred in but one of the above series of Alexander operations, and in this case it was limited to the subcutaneous fat. Infection took place in this case, I am satisfied, through the efforts at cleansing the vulvar region after the performance of the Alexander operation, preliminary to the repair of a complete tear of the perineum. It is frequently stated that the pubic region and the groin are especially prone to suppuration. This experience and the fact that in none of my operations for inguinal or femoral hernia has suppuration occurred make me confident that suppuration is not due to the region involved, but to faulty technique on the part of the surgeon, or what is more usually the case, the failure to apply a fixed dressing. This is a point of such importance as to be worthy of emphasis. The double spica bandage which is commonly employed by surgeons to retain the dressings in place is objectionable unless removed after twenty-four or forty-eight hours, because it is inevitable that the bandages about the inner surfaces of the thighs will become soiled when the bladder and bowels are evacuated. For the Alexander operation the same dressing is used that is employed for the median celiotomy wound, with the exception that in addition to the transverse adhesive straps, others are placed around the inner surface of the thighs, then from within outward, and below upward across the lower portion of the abdominal dressing, the outer end of the straps being applied to the posterior surface of the pelvis. These straps keep the dressing from slipping up and exposing the lower ends of the pubic wounds. The nurse has instructions to watch these straps and the dressing. If the straps become loosened, fresh ones are applied, and if the dressing is soiled, the wound is immediately freshly dressed.

From May 28, 1898, to October 10, 1899, 224 celiotomies and Alexander operations have been performed in which the tier method of suturing the wound was employed. In this series of cases catgut only was used. Herniotomies have not been included in this list, and operations in which through-and-through sutures have been employed have been excluded. Two celiotomy wounds and one Alexander operation wound suppurated, or 1.3 per cent. In addition, there was a failure of union at a small point in the skin in three cases. In one patient, a fat woman, the wound was torn open through the fatty layer by the patient turning on her side. The edges of the wound were brought together by adhesive plaster, and healing occurred without suppuration. In one patient, during a violent fit of vomiting on the fourth day, the wound burst open, allowing the escape of several feet of intestine. The intestine was washed off, the wound reclosed, and healing by primary union was obtained.

[4] Alexander's Operation, American Gynecological and Obstetrical Journal, May, 1899.

In one case a post-operative intraperitoneal abscess discharged through the abdominal wound some weeks after operation. In two cases of tubercular peritonitis primary union was obtained, but the chromicized catgut suture caused suppuration about six weeks after operation, and was subsequently discharged. One case of hernia is known to have occurred in the above series of cases, and in a second case a hernia has appeared about an inch above the incision. The case of this hernia is a long-standing diastasis of the recti muscles following pregnancy.

In comparing the results secured with buried silkworm gut as contrasted with the exclusive use of catgut, the record is perhaps rather in favor of the silkworm gut, although the discrepancy is not great. The very distressing accident of the eventration of the intestines on the fourth day would not have occurred had silkworm gut been used as a buried suture, nor do I believe it will often occur with the present method of suturing. The patient was one having an especially vigorous muscular system to produce the powerful intra-abdominal pressure which burst open the wound, and the probabilities are that the continuous suture which closed the rectus muscle was cut by the needle when closing the aponeurotic layer — an accident which might well happen. This is the only accident of the kind which has happened in my experience, no matter what method of suturing was employed.

Delayed suppuration in two patients who were operated upon for tubercular peritonitis is interesting as showing that the process of encapsulation, or the gradual process of absorption of chromicized catgut, does not take place so readily in persons of reduced vitality. In these two patients the catgut acted as a foreign body and produced suppuration, presumably without infection, as suppuration did not take place until at least six weeks after operation. I feel quite satisfied that it is much easier for the tissues to encapsulate a fine silkworm-gut suture than it is to absorb a medium-sized chromicized catgut suture.

The foregoing report warrants the conclusion that in celiotomy wounds which can be closed without drainage suppuration can be reduced to two per cent. or less, and that post-operative ventral hernia can be reduced to a fraction of one per cent.

As the paper has been very discursive, I would suggest the following points for discussion: (1) The histological basis of the various methods of suturing wounds of the abdominal wall; (2) the relative advantages of different suture materials; (3) the relative advantages of different methods of closing wounds of the abdominal wall; (4) methods of suturing in Alexander's operation; (5) sterilization of the hands; (6) the use of rubber gloves as a preventive of wound infection.

In conclusion, it is only left for me to express my appreciation of the honor you have conferred upon me in inviting me to address your Society this evening, and to thank you for your attention.

Women Medical Students in Paris. — There are, according to the *Medical Press*, 129 female medical students at Paris, of whom 91 are Russians, 29 French, five Roumanians, two Germans, one Swiss, and one British. In Paris, women are placed absolutely on the same footing as men.

ABSTRACT OF PAPER ON "FURTHER EXPERIENCE WITH THE OPERATIVE TREATMENT OF ANTEFLEXION."[1]

BY W. L. BURRAGE, M.D., BOSTON.

Two years ago the writer read before the Obstetrical Society a paper on "Division of the Uterosacral Ligaments and Suspensio Uteri for Immobile Retroposition with Anteflexion," in which he reported nine cases treated by curetting, division of the uterosacral ligaments through an abdominal incision and suspensio uteri.

In the present paper he reviews his private notes of all operations performed for anteflexion, 92 cases, analyzes the remote results and announces his conclusions.

Retroposition with anteflexion is defined anew. It is a uterus situated as a whole in the back of the pelvis, that is to say, close to the sacrum, and flexed forward, the flexure being in the body of the organ, in the neck, or in both. The tissues of the uterus at the angle of flexure may be so firm, so altered in consistency by disease that the uterus cannot be straightened (pathological anteflexion), or they may be soft and more nearly normal, and in this case the uterus may be restored to its natural form (congenital or, more properly, puerile anteflexion). A condition of anteflexion is normally found in the little girl, but it is not present in the fetus, therefore we should speak of puerile rather than congenital anteflexion. The uterus which is anteflexed is generally retroposited also and its mobility limited. Shortening of the uterosacral ligaments has been heretofore too generally overlooked by writers on this subject. An anteflexed uterus held in the back of the pelvis close to the wall of the sacrum cannot be straightened because there is no room for the backward excursion of the cervix. The posterior attachments of the uterus limiting its mobility must first be divided.

Anteflexion would seem to be a persistence of a puerile status due to arrest of development coupled with inflammatory action in the uterosacral ligaments and uterine tissues. The source of the inflammation is not clear. Uterine discharges dammed up at the internal os by the flexure at that point and forced through the tubes into the peritoneal cavity, and the passage of hardened fecal masses through the rectum between the uterosacral ligaments, have been suggested as causes. An increase of intra-abdominal pressure from tight lacing or from a chronic accumulation of gas in the intestines, and acting on the posterior face of the body of the uterus, undoubtedly contributes to the formation of anteflexion in certain cases.

The uterosacral ligaments are described in the anatomies as consisting of muscular and cellular tissue and folds of peritoneum. They extend from the pelvic wall near the second piece of the sacrum on either side, and come together on the posterior surface of the uterus at about the level of the internal os in the form of a V. In testing the size and strength of these ligaments in the class of cases under discussion by the bimanual touch and in dividing them, both through an abdominal incision and through a vaginal incision in the cul-de-sac, it is often astonishing to find them so thick and their structure so tough and unyielding. They are ligaments indeed, and it is plain why ventral

[1] Read before the Obstetrical Society of Boston, November 21, 1890.

suspension of the uterus is a failure where these shortened ligaments are ignored. No artificial ligamentous attachment of the uterus to the anterior abdominal wall can hope to equal the pull of these strong posterior guys.

Traces of past inflammatory action in Douglas's cul-de-sac may be observed in some patients in the form of wrinkling and thickening of the peritoneum over and about the ligaments, and in an irregular course of the ligaments.

Retroposition with anteflexion is a common disease in the experience of the writer, 10 per cent. of all of his private cases having been so diagnosed. B. S. Schultze has described this as occurring frequently. It most commonly causes distressing symptoms in young women under thirty years of age, and they suffer from dysmenorrhea, scanty and irregular menstruation and an upsetting of the balance of the nervous system, together with a certain amount of deterioration of the general health. Palliative treatment with drugs and with local measures for depletion of the uterine organs should be given a trial. Stem pessaries are dangerous and other pessaries are useless. Local treatment over a prolonged period of time is not to be counselled in a majority of young unmarried women.

The 92 cases are analyzed with reference to a straightening of the flexure in the uterus, which was marked in every instance, and as regards the curing of dysmenorrhea, the common symptom.

Thirty-six cases treated by curetting and by massage to the shortened uterosacral ligaments where necessary: Twelve of the 20 cases heard from were relieved of dysmenorrhea as a result of the operation, and eight were not relieved. Most of these cases were treated by thorough dilatation and curetting and irrigation of the uterine cavity with salt solution, then drying with gauze and swabbing with pure carbolic acid. It was not noted that the uterus was permanently straightened in any case, although in most instances a previously tight canal remained patulous several months after the operation.

Six cases curetted and massaged and an Alexander operation done at the same sitting: In two the results were unknown. In the remaining four the uterus was straight or very slightly flexed. The dysmenorrhea was relieved in three, unrelieved in one.

Twelve cases of curetting and division of the shortened uterosacral ligaments through an incision in the vagina (colpotomy): Results unknown in four; uterus straight in four; relieved of dysmenorrhea, three; unrelieved, five.

Four cases of curetting and cutting the uterosacral ligaments by colpotomy and an Alexander operation: Results unknown in two, the other two were relieved. One of the latter became pregnant and the other had an anteflexed uterus two years after.

Six cases of curetting and E. C. Dudley's operation on the cervix: Uterus straight in five, flexed in one; three relieved, two not relieved, and had subsequent abdominal operations with relief. The sixth case had fungous endometritis and complained only of menorrhagia. The uterosacral ligaments were not appreciably shortened in these six cases.

One case of curetting and amputation of the cervix and one case of curetting, Dudley's operation and division of the uterosacral ligaments through the abdominal incision and suspensio uteri are too recent to give results. One case of evacuation of a pelvic abscess behind an acutely anteflexed uterus was of interest, because when the abscess cavity had closed the uterus was perfectly straight.

Three cases of curetting and removal of both tubes and ovaries for extensive disease, followed by suspensio uteri after cutting the uterosacral ligaments: Uterus flexed in all.

Twenty-two cases of curetting, division of the uterosacral ligaments through the abdominal wound and suspensio uteri: Immediate results show uterus perfectly straight in six, slightly flexed in 13, and three still in hospital; remote results in 13, uterus straight in four, slightly flexed in six, and sharply flexed in three; dysmenorrhea relieved in nine.

As a result of his experience in the operative treatment of anteflexion the writer lays down the following rules for his guidance in these cases:

(1) In anteflexion without ovarian or tubal disease, and free from shortened uterosacral ligaments or posterior adhesions, dilatation, curetting and Dudley's operation or amputation of the cervix, with a preference for the former.

(2) In anteflexion with retroposition and shortened uterosacral ligaments or posterior adhesions, and without ovarian or tubal disease, dilatation, curetting and division of the uterosacral ligaments or adhesions by colpotomy and Dudley's operation or amputation of the cervix, with a preference for the former. Amputation of the cervix is a useful operation where the cervix is very long and also where there is extensive erosion of the crown of the cervix. In married women in both of the foregoing classes dilatation and curetting without other operation are sufficient, because pregnancy will usually straighten the uterus and stretch the ligaments and adhesions. Should pregnancy not supervene within a number of months, and should the symptoms persist, another curetting and Dudley's operation, with or without division of the ligaments, may be done.

(3) In anteflexion, with or without retroposition, having ovarian or tubal disease, dilatation, curetting, Dudley's operation, and suspensio uteri, the uterosacral ligaments being divided through the abdominal wound if they are shortened and whatever may be necessary done to the ovaries and tubes.

THE GASTRO-INTESTINAL TRACT IN NERVOUS DISEASE.

BY F. SAVARY PEARCE, M.D.,

Instructor in Physical Diagnosis, University of Pennsylvania; Physician to the Medical Dispensary, St. Agnes' Hospital, Philadelphia.

THE intimate relation between the central nervous system, organs, and functions of the body especially, cannot be too forcibly emphasized. Stress is to be laid upon the oblivion existing through the inexact knowledge of the anatomic relation between the cerebro spinal, or system of animal life, so-called, and the ganglia sympathetica, or system of organic life, as we know it to be, and especially the inexact understanding of the anatomy of these most delicate ganglia and nerve fibres and of their intricate inosculations; that is, of the sympathetic fibres about the important organs of the body. Recent anatomical and physiological experimentation, now being pursued through the aid of vivi-

section, is proving more and more the wonderful rôle played by the "abdominal brain," as some anatomists have dignified the ganglia of this to be. Bearing in mind the wonderful controlling influence of the sympathetic nervous system, as shown by the preservation of life under profound anesthesia, the justice of styling these ganglia subconscious brains is the more appreciated; and the wonderful influences even then of its reflexes upon important centres, as respiration, the writer has recently had demonstrated to him in a male, aged thirty years, whom he had operated on for fissure *in ano*. While under profound etherization the respirations could be controlled (inhibited) by wide dilatation of the sigmoid flexure by means of a long bivalve speculum. Perhaps one great reason why the sympathetic system has not been given enough import in practical medicine and therapeutics is because morbid conditions of the same, as in health, do not give rise to any painful sensation, and, therefore, when pain *does* occur it is directly of cerebrospinal origin. We very often, therefore, fail to seek the real reflex primogenesis of morbid states presenting symptoms for relief. In another place [1] we have emphasized the importance of considering the sympathetic system's influence in the causation of neurasthenia through disturbance of the reproductive organs — a subject that has been widely discussed and must be accepted as proven. While similarly, of course, co-relation of the great laboratory of the body through the sympathetic to the cerebrospinal axis, both physiologically and pathologically, needs no scientific advocate to further establish it, yet specific cases bearing upon gastro-intestinal disorders and nervous disease may prove of some value for obtaining a more widespread recognition and a proper therapeusis of the less manifest diseases of the nervous system which still *do* have the same pathogenesis. Admitting the difficulty of ascertaining cause or effect frequently, even where there is evident co-relation between nervous disease and gastro-intestional disorders, the point we wish to consider *especially* is to determine *how many* cases are relieved by *treatment* of the primary or secondary gastro-intestinal state; and more scientifically to seek out given cases of nervous disease greatly aggravated by the intestinal trouble, or, indeed, entirely caused by it. This leads back to the broad study of heredity and conditions of environment, and much clinical experience. In a paper with Dr. Wharton Sinkler, on "Family Diseases," [2] we drew conclusions that heredity could be considered from a statistical review of a large number of cases (16,500) as one or more in 80; although, if the most accurate history of our cases could be obtained, much higher.

Savill (1899), in his recent monograph on "Neurasthenia," adds zest to investigation of these allied nervous states of the human body.

Impetus in the study of aberrations of kidney excretion — not an index of renal disease, however — was first given the writer through making the urinalyses in a large number of cases of nervous diseases in the practices of Drs. S. Weir Mitchell and John K. Mitchell. The results of uric-acid findings have been published, and while indican is tested for in almost all cases we have not up to this time made careful analysis of its possible import in nervous disease.

[1] Neurasthenia: Its Co-relation with Pathology of the Female Organs, with H. D. Reyea, M.D., Annals of Gynecology and Pediatry, September, 1898.

[2] Journal of the American Medical Association, February 10, 1900.

The whole subject of irritation and auto-intoxication, *per se*, as causal factors of disease of the nervous system is most intricate in its exact determination for the therapeutic point of view, which is our *most to be desired* knowledge. For instance, in a case of large ovarian tumor, as reported by Beyea [3] recently, to my mind, the glycosuria was due to irritation of the glycogenic centre in turn *preventing* metabolism. The diabetes here disappeared after removal of the tumor.

FOURTEEN DETAILED CASES AS BASIS OF THIS STUDY.

Case I. M. B., female, age twenty-two years; married, one child living; no miscarriages; reported March 19, 1898, suffering with what she styled splitting headaches for about three months, worse toward evening and the dark hours. The headaches had begun with constipation, which, when first seen, was very troublesome. She suffered from anorexia, insomnia and exhaustion, tongue was slimy, coated and flabby, tooth indented, pulse 120 per minute, heart weak, no murmur. We could find no ocular or aural cause for the head symptoms. She was placed on a liquid diet, given blue mass, gr. v, at bedtime for several days, and tonic of tr. nucis vomicæ and soda bicarb. before meals, and semi-rest treatment was enjoined. Improvement followed immediately. At the end of two months she considered herself a well woman, having no head symptoms, and the bowels remaining in normal condition.

Case II. J. J., reported April 2, 1898; male, age fifty-three years, shoemaker, alcoholic, — following exposure awoke with pain in arms and down left leg, accompanied by numbness in left side of the body. He never had had acute rheumatism. With the incipiency of the pain described he had had an attack of gastritis, followed by lienteric alvine dejections of the gastric fermentation. Antiseptic treatment to the intestinal tract dissipated the pain and subjective numbness within twenty-four hours. Although this patient complained of dulness of vision for a week after the attack, to our mind the case presented a complex of alcoholic depression, to which was added intoxication from ptomaine poisoning. In the history it was ascertained that the amount of alcohol he had taken previous to this attack had produced little or no impression on the nervous system. The peculiarity in this case was the objective and subjective coldness of the left arm, leg and entire left side of trunk, probably showing disturbance of the caloric centres unilateral in the higher nervous system. At the end of two months the man seemed back to normal health in all ways — perhaps some of hemichoreic movements may be excited by the unstable neurons later in the case.

Case III. R. I., reported May 28, 1898; female, age forty years; Hebrew; five children living, three dead; complained of *dull vertex headache*, periodic about once in three months, lasting several days, accompanied by insomnia; no rheumatism; no other pains complained of; bowels said to be regular; urine high-colored, *contained indican in excess;* appetite fitful. She is a plethoric woman, heart is feeble; however, no organic lesions can be found excepting great relaxation of the abdomen and dilatation of the intestinal tract and fermenting contents. The use of magnesium sulphate to thorough cleansing of the intestinal tract, with occasional use of acetanilid, caffeine and camphor monobromate as a nerve depressant, together with massage of the abdomen and restricted diet, and occasionally high flushings of the colon with lime-water solution, produced immediate permanent improvement.

Case IV. M. G., reported July 2, 1898; female, age thirty-five years; single; complains of general nervousness and nerve tire, easily exhausted, with considerable vertical headache, growing worse toward evening; suffered from indigestion; eructations of sour stomach contents; bowels are moved daily, although there is constant feeling of tightness through the abdominal content, with distention. This woman's diet was cut down to liquids largely, and nux and

[3] College of Physicians of Philadelphia, Section on Medicine, December, 1899.

soda mixture was given before meals, with very rapid relief of general nervous state and headache. Five-drop doses of strong acid nitrohydrochlor. were continued for one month.

CASE V. J. S., reported August 6, 1898; male, age twenty-nine years; no history of nervous disease in family; complains of pain in head in occipital region, lasting one week, *completely incapacitating* him for work. There is no history of specific disease; kidneys are normal, his physique being powerful; gave a history of extreme constipation for some months, and was a great meat eater. The only pathological state of the urine was of excessive indican. He was put on restricted diet and given sodium salicylate, gr. x., t. i. d. Within a month this man got perfectly well of the toxemic headache, considered to be due to potomaine intoxication aggravated by excessive proteid diet.

CASE VI. C. K., reported December 3, 1898; female, age thirty-nine years; married, eleven children, six living, others died of marasmus. Patient complains of frontal headache for the past two weeks, which comes on in the morning and disappears in the afternoon; also complains of vague pains in extremities and of *general nervousness*. Headaches begin about 9 A. M. and last to 4 P. M. Correcting a hyperacidity of the stomach with mild daily catharsis very much relieved her condition at the end of four weeks — that is, the headaches did not last so long, but seemed quite as severe in their several hours' duration. This woman seemed entirely well two months after beginning treatment. During the summnr of 1898 she relapsed into the same condition of intestinal indigestion, with *indicanuria*, to again be entirely relieved in the fall by a mixture of charcoal, gentian and sodium bromide. Again, having had a relapse, living as she does in poor hygienic surroundings, each time has been relieved by intestinal antiseptics. It should be said there were no other causes to be found; menstruation was normal, and the eyes presented no error of refraction.

CASE VII. N. D., reported March 25, 1899; widow, age thirty years; two children, living and well; no miscarriages; has been very constipated for some weeks; her head began to distress her much across the frontal region, beginning several weeks before reporting for treatment. *Pain is of dull nature*, gradually growing worse toward evening. This patient was much improved by the use of bromide and gentian, and after full correction of intestinal torpidity the headaches entirely disappeared. I take it that the absorption of ptomaines from the intestinal tract, and of the improperly eliminated metabolites of the system passing through the sensitive dura mater were the exciting cause of the cephalic distress (lymphostasis).

CASE VIII. M. P., reported April 11, 1899; female, age sixty-five years; complaining of pain in the lower lumbar region and general feeling of tire, accompanied by violent wind dyspepsia, and labelled "disturbed metabolism." Under the use of gentian, nux and soda mixture, with the limitation of diet to milk and proteids, and with the stimulating effect of the static current down the spine, she was entirely relieved in two and a half months of the general toxemic state. The association of dyspepsia and rheumatism seem to be proven in such a hybrid case as this one. We have no doubt that many cases of rheumatism are precipitated by catching cold, since the retention theory of the genesis of a "cold" would tend to show the disturbance of metabolism acting through the nervous system, and would be sufficient cause for the rheumatic state. Some form of organism *may* be the determining factor of acute rheumatic fever, and may also be a potent cause. Certainly the subject of rheumatism is still in a state of theoretic speculation. Nervous origin is, undoubtedly, a large basic cause in this disease so closely allied to the conditions of waste product pains of disturbed metabolism; for the nervous system must control the proper absorption and elimination of leucomaines, etc, in health and disease.

CASE IX. L. L. (private), reported May 11, 1898; female, age thirty-five years; for three years has been suffering from excessive nervousness associated with extreme constipation, bloating of the stomach and wind dyspepsia; *urine contained a large amount of indican;* her sleep was much disturbed with vague distress in the head, much aggravated when bowels were not relieved by cathartics. Use of bromide of soda in moderate doses, with trional as an hypnotic, much improved her "general nervousness." But it was not until full relief of the gastro-intestinal condition, after several months in treatment by means of regulated diet, massage to the abdomen, special as well as general, and the use of salol as an intestinal antiseptic, that she began to gain flesh and lose permanently the general nervous condition she had been in so long. The difficulty in such a case as this is to trace the *post hoc* in the vicious circle undoubtedly set up; and yet we feel that, clinically, restoration of health was largely influenced by correcting the function of the digestive tract.

CASE X. F. S., reported to the Howard Hospital service of Dr. J. Madison Taylor, July 14, 1897; female, age seventeen years, single; came to us at the nervous clinic, having been referred from the medical clinic on account of what was diagnosed as toxemic headaches, the ordinary methods of relief having failed. As the girl came into the room she gave a peculiar sigh, due to a forced inspiration, and fell on a chair unconscious, frothing at the mouth, in clonic and then tonic spasm of the entire musculature. She was profoundly unconscious, and pallid in the attack, and was dazed for half an hour after recovery. It was then learned she had five of these seizures within a year. She was particularly waxy in appearance, and there was acne over the forehead and nose. She complained pretty constantly of frontal headaches, was extremely constipated, and suffered much from epigastric distress, although the trio of signs of epigastric ulcer were eliminated. The girl complained of tenesmus and general abdominal distress, much increased at the time of attempted defecation. The skin eruption seemed to be aggravated, and to spread in a more generalized hyperemia about ten o'clock in the mornings, increasing to acne about three o'clock, when small white vesicles came out over the face and neck, this more acute syndrome of epidermic disorder again abating toward night. The patient was first put on a tonic, and the case studied carefully from day to day. It was soon found she complained of general muscular soreness without any real rheumatism. We now put her on small doses of potassium iodide and sodium salicylate, and began to pay special attention to the bowel condition, as examination of the urine revealed large quantities of indican present. High enemas were resorted to, by the use of the long rectal tube, adding glycerine to the alkaline solution of soap. It was four months before any approaching normality of the intestinal tract was obtained, and with it the appetite improved, persistent acne was bettered, while the transient erythroderma had entirely disappeared. The patient was now put upon iron in moderate doses (Blaud's pill, gr. v, t. i. d.), and the various laxatives used, as the great torpidity required frequent changes of cathartics to produce any effective results. It should be said no stricture of the lower intestine could be made out. While the girl complained constantly of stomach distress, since the headaches were better and no eye lesions or other cause having been found for them, we felt we were on the right track. During the following year the patient had but one epileptic seizure; the blood count ran up from the original anemic condition of 3,200,000 red blood corpuscles to 4,800,000 red blood corpuscles, and while iron could not be taken for many weeks at a time, the ability to digest food through the use of caroid and other digestants favored hemogenesis. The patient has had *no epileptic seizure for twenty-two months*, and seems at the present writing to be about well, so much so that she was married on December 13, 1899. The urine analysis *failed to detect indican* at the present time, and the gastro-intestinal function is entirely normal.

CASE XI. A. L., single, age fifty-two years, always a delicate, refined woman, was sent to me by Dr. Stewart, of Allegheny, January, 1899, suffering from tormenting headaches not of a migraine type, but being constant, dull, and

splitting in character all over the cranium. She has been violently constipated *for twenty years*, but paid little or no attention to it; doing with little food; having generalized swelling of the face, hands, and lips at times in the mornings when she was at her work. The urine was normal save for much indican present. She frequently "threw off" quantities of bile. There is some tenderness over the liver, and gastric irritability, with gastroptosis. She is in extreme neurasthenia. Climacteric established at fifty years of age, but did not seem to influence headaches, constipation, nor her generally poor metabolism. She was placed on high enemas, free use of cascara and abdominal and general massage, occasional lavage, and trophonine as a tissue builder. Improvement was slow but steady. Her eyes were not in any way causative of headaches, being simply presbyopic and fully corrected. After six months she had become very well indeed. I saw her in Allegheny on December 22, 1899, after a two days' headache, apparently precipitated by constipation, with high pulse tension, which by digestants we are with some success treating. The use of molasses in this case will precipitate headaches the next day, I take it, due to fermentation thus set up.

Case XII. C. S., age fifty years, business man in large responsibilities for years, with an original weak constitution, — nervous. Has had gastritis off and on for twenty-five years. Has been treated with great benefit on several occasions by the late Dr. William Pepper and by Dr. Wharton Sinkler, the latter gentleman placing the patient on semi-rest treatment, sulphocarbolate of zinc and the exhilarating effect of hydrotherapeutics at the Infirmary for Nervous Diseases. At this time the total acidity of the stomach was four per cent., and showing slow digestion in the lavage fluid drawn off two and one-quarter hours after a test meal. There was no albumin or glucose in the urine, but an excess of uric-acid crystals. The man also had irritating piles, removed by the surgeon. His bowels became regular, and abdominal distress largely disappeared. He gained much in weight, and after a number of weeks' treatment went back to Ohio immensely improved, May, 1899. While in Ohio, December 24th, I was called to see him; found all signs of returning neurasthenia, gastric atony, and *indicanuria*. He had lost much flesh. Was belching continuously. Attack said to be due to cold. Blistering over stomach was now resorted to, and the toxic condition of the urine treated by salol. The patient has improved some up to date, and indicanuria has disappeared. Undoubtedly in this case auto-intoxication plays a rôle in semeiology.

Case XIII is that of a female, age seventeen years, white, single, suffering one year from atonic dyspepsia and persistent supra-orbital neuralgia for six months. She is of bilious temperament. Cardiac arrhythmia prominent. Gastro-intestinal therapy cured in one month the head pains.

Case XIV. Anna G., German, single, age twenty-six years, reported to my clinic at St. Agnes' Hospital, November 9, 1899, suffering from constipation since sixteen years of age, frontal headache, acne, and lethargy. The latter two symptoms were always worse in the morning, and recovered some from them as she forced herself out of doors or to her work. Is always worse after a hearty meal, when she has a sense of sinking. Bowels are moved daily, but she has a sense of insufficient evacuation always. Stomach is dilated down to the umbilicus. *Indicanuria marked.* Indigestion is always made worse by worry or overwork. If she catches cold the bowels are always made more costive. Boulimia and evidences of slight catarrhal gastritis. She was put on restricted diet, given sodium phosphate one drachm before breakfast, acid nitrohydrochlor. dil. gtt. x. a. c. with a tonic. This girl has very rapidly convalesced from her miserable condition, and is happy in the zest for work.

A sister is undergoing such a therapeutic régime with good effect.

This case shows the *mixed* class we have styled, — that is, when neurasthenia and auto-intoxication exist contemporaneously. The combined neural upbuilding with intestinal antisepsis and hygiene we feel are equally responsible for the great improvement up to date. Such a case as this might be termed one for the neurologist or for the gastrologist, if we look not broadly on the medical horizon.

Conclusions.—From the foregoing clinical study it seems pretty clearly demonstrated to the writer that we have three classes of disease in which the nervous system is more or less intimately influenced by gastro-intestinal disorder and usually of a toxic nature.

(1) (*a*) Neurasthenic states, general or in localized areas of distribution (most common); (*b*) where organic changes are present in the nerve cells (sclerosis). Both of these influences certainly lower resisting power and cause improper distribution of nerve force to the gastro-intestinal tract. This leads to dilatation and perversion of the enteric secretions, thus giving rise to fermentations of the stomach contents, etc., products of which are reabsorbed, further disturbing the metabolism and aggravating the symptoms of neural disorder.

(2) Cases where long-continued gastro-enteritis causes organic change in the mucosa and gastro-intestinal glands, including the liver and pancreas, of course — thus making the primal point of disease an irritating fermentation, with the elaborations of toxins. These, with the hyperacid secretions, especially of the stomach content, are in part absorbed into the system, producing a constant auto-intoxication, as would excessive tobacco or any other poison, — thus intoxicating through the blood the central nervous system until we have finally, in slow process, asthenia set up in the neurons, innervation of the gastro-intestinal tract at that moment being perverted through the efferent, specialized, and trophic nerve twigs.

(3) There must be a mixed class of cases in which neurasthenia, so-called, or organic nervous diseases are associated, *pari passu*, with disorders of digestion of a functional or organic nature. Admitting the difficulty of determining when (1) and (2) exist — even when the cause and effect certainly do maintain — for this reason it seems logical to state that a large number of cases placed in the *third* category belong by right to the preceding *two* subdivisions. The more close histories of our cases we secure, the more exact clinical studies made of symptoms and signs in the individual case, together with careful analyses of the secretions and excretions of the body, thus utilizing the associated import of such phenomena as *indicanuria* for indices, will the better results be obtained in *treatment*. So, also, will such closer observation in the direction noted more surely place the association of neural and somatic diseases out of the less intricate classification we have termed *mixed*. The individual case study as to heredity, diathesis, or temperament, must needs be broadly taken into account. There does seem to be the greatest reason to assume the *acid*, *neutral*, and *alkaline* temperaments, with their predispositions and peculiar immunities, in drawing any conclusions of the case.

An admirable article by Dr. Albert E. Sterne in the *Philadelphia Medical Journal* of December 2, 1899, elaborates this, as it seems to us, very important side of medicine. Nor should we fail to recognize that secretions and excretions are influenced by the emotions, — for example, serous diarrhea produced through emotion or overwork, as shown in the noviti-

ate to the examiner's room, — or application to hard mental labor in a neurasthenic subject. These physiological phenomena are shown in full light by the work of Darwin on "Expression of the Emotions in Man and the Lower Animals," hence the subtle metaphysical influence must be weighed in any case along with the accurate scientific knowledge indicated.

The more we study the sympathetic nervous system, the more clearly will morbid phenomena, such as the association of biliary disease or irritation causing disturbance of menstruation, of serous diarrhea substituting menstruation, or, indeed, vicarious menstruation, be better understood. The fact that pain seldom enters into these disturbances as a prominent factor at least misguides the patient as to interpreting his being ill, and the physician, too, in determining the conditions from the limited objective signs and symptoms alone.

Addendum.—Aside from the subject of intoxication, of course other irritants of a mechanical nature do produce nervous symptoms. I know of a case in charge of a Western physician where chronic eczema was cured by stretching a stricture of the rectum, and another case of epileptic convulsions ceasing after a cure of a rectal fissure which had been long neglected.

A similar case has been recently reported in the *Boston Medical and Surgical Journal*, December, 1899. The writer wishes here to refer also to the *New York Medical Journal* for July 29, 1899, in which he has reported a case of hebephrenia, with all its typical vagaries, undoubtedly due largely to persistent constipation. The girl is perfectly well to-day.

A METHOD OF DETERMINING THE DIGESTIVE POWER OF GASTRIC JUICE, AS WELL AS THE ABSORPTIVE POWER OF THE STOMACH.

BY A. E. AUSTIN, A.M., M.D., BOSTON,
From the Chemical Laboratory of Tufts College Medical School.

IN considering the products of gastric digestion, it is, of course, first necessary to separate them into their constituent parts. First, we have soluble albumin, a substance which never exists except where there is a lack of HCl. Then we have acid albumin, a loose combination of albumin with this acid, and as final or end products, albumose and peptone. It is found, for all practical purposes, unnecessary to separate these two products, since both are equally readily absorbed. Whether there exist, also, anti- and hemi-groups of these latter products is unimportant to the clinical consideration of the subject, for both are precipitated by the same reagents and have all their other properties evidently similar.

To separate these products, it is first necessary, where no free acid is present, to add a drop or two of HCl and heat to boiling. Then sodium carbonate is added, until the acid albumin is completely precipitated. Now, by process of filtration we can readily separate the acid albumin from the albumose peptone. Whether all the native albumin is wholly removed can be readily demonstrated by adding some nitric acid to this filtrate, and warming. If albumose peptone only is present, the precipitate is redissolved. If native albumin is present, the precipitate becomes firmer and more copious. This precaution should never be omitted in testing for albumose peptone. In the quantitative estimation of albumose peptone two methods may be employed: an absolute, known as Kjeldahl's, and an approximate method, which in this article we propose to demonstrate. The Kjeldahl method consists of converting the nitrogen in the albumose to the sulphate of ammonia by means of cooking with strong sulphuric acid, freeing the ammonia by the addition of sodic hydrate, and distilling it into an acid solution of known strength. By back-titration, with an alkaline solution of known strength, we can determine the amount of ammonia, and from this calculate the amount of nitrogen, and also of the albuminous product examined. This process, as can be seen, is extremely cumbersome, and entirely unsuited to clinical methods. It has its value, however, in enabling us to keep a control over all approximate methods, and to determine how far they depart from the absolute. To do this, it is necessary to know the percentage of nitrogen in albumose peptone, of which there exist only a few reports in chemical literature, so that we found it necessary to re-establish this fact from personal observation. Albumin possesses about 16 per cent. of nitrogen, but from the table appended below, it will be seen that the amount of nitrogen from albumose peptone is very much less than this. As an instrument of approximate estimation, the centrifuge was chosen, as its graduated tubes furnish a very good means of comparison between the precipitation and the solution in which it was precipated. As a precipitant, Esbach's solution was first chosen, but proved unsatisfactory from the small amount of precipitate which it produced. On the contrary, phosphotungstic acid, watery solution, 1–20, and HCl were found to give a copious white precipitate, and to precipitate completely the albumose peptone held in solution. The necessity for comparison of the centrifuge method, and the absolute determination by Kjeldahl's method will be evident to all when the following results are compared:

Experiment 1. — Several solutions of Merck's peptone were prepared, varying in amount from .1 gramme in 100 c. c. of water to 1 gramme in 100 c. c. of water. It was found that, in order to keep these in perfect solution, a few drops of alkali were necessary, and

TABLE I.

KJELDAHL.			CENTRIFUGE.	
Strength of Solution. Per cent.	Nitrogen in Grammes. 10 c. c.	Percentage of Nitrogen in Albumose Peptone. Per cent.	Reading of Graduated Tube. 6 c. c.	Calculated per cent.
.1	.00168	11.9	.3	.1
.2	.0028	14.8	.6	.2
.3	.0032	10.7	.9	.3
.4	.0049	12.2	1.2	.4
.5	.0065	13.1	1.5	.5
.6	.0072	12.1	1.8	.6
.7	.0071	10.2	2.1	.7
.8	.0092	11.5	2.4	.8
.9	.0091	10.1	2.7	.9
1	.0116	11.6	3.4	1.1

by means of this, perfect solution was maintained as long as the time requisite for manipulation demanded. Of these solutions, 6 c. c. were now taken in the graduated tube, a few drops of HCl added, and a watery solution of phosphotungstic acid added up to the 10 c. c. mark. The tubes were then placed in

the centrifuge, and rotated rapidly by hand for five minutes, after which the precipitate was found firmly impacted in the bottom of the tube, and its amount in fractions of a cubic centimetre could be easily read. As a control, 10 c. c. of each solution were treated by Kjeldahl's method, and the nitrogen determined and reckoned in percentage of the amount of albumose peptone used. The results of these determinations can be best displayed in the foregoing table, which we will call Table I.

From these determinations with known quantities, we see that the amounts registered by the graduated tube correspond very closely with the known quantities of albumose peptone, and that from these we can very easily devise a method of calculation. If we divide the amount registered by the tube by 300 it will give us the rate per cent. of albumose peptone. For instance, if the tube reads 1.5 c. c. and we divide this by 300 we find that the resulting product is .005, which is, of course, similar to .5 of 1 per cent. Still more briefly, we may divide the reading of the tube by three, considering the result as tenths of 1 per cent. Another point was discovered, that after a concentration of .6 of 1 per cent. is reached, it is more desirable to dilute with an equal amount of water, whereupon, of course, the resulting product must be multiplied by two.

To this lack of dilution, undoubtedly, the excessive result in the last determination can be attributed. From the Kjeldahl estimate, we learn that the amount of nitrogen apparently varies, but this variation is probably only apparent; resulting perhaps, from the imperfect distribution of the albumose peptone in these solutions, and also from error in calculation. This difficulty, of course, could not occur in filtered gastric contents. As an average of these ten estimations, we learn that albumose peptone contains 11.7 per cent. of nitrogen, but for convenience in future work we have adopted 12 per cent. as a ready factor of calculation. The degree of firmness possessed by the centrifuge precipitate depends, of course, upon its speed and the length of time; but as we regard the revolutions of the centrifuge as about 3,000 per minute, which can be readily procured by turning the handle with moderate rapidity, we have 15,000 revolutions as a basis for our reading. With the electric centrifuge, the revolutions can be more readily regulated; this would not present the slightest difficulty.

Experiment 2. — In order to apply these methods to actual gastric contents, we have, of course, to simulate digestion in the stomach as far as possible with our laboratory appliances. The ingredients of gastric juice we possess: HCl, pepsin and water. Heat of the temperature of the body is maintained for a long period with our brood oven. But absorption of digestive product we cannot simulate, nor can we simulate the peristaltic action of the stomach. Apart from these hindrances, which are unavoidable, artificial digestion in the laboratory must produce the same results as natural digestion in the stomach; so that in order to fit our method more accurately, various solutions were prepared which consisted of .1 gramme of pepsin, 100 c.c. of water, and .5 gramme of albumin. The albumin was dried, and in scales. The HCl was present in varying amounts, beginning with 2.5 parts per 1,000, and ending with .25 parts per 1,000. The period of digestion was invariably twenty-four hours. As a control, there was also prepared a digestion with the same elements, except pepsin, and in place of that, a vegetable proteolitic ferment was used, whose digestive power it was desired to test. After the period of digestion was over each of these solutions was tested for the presence of free acid, soluble and acid albumin were removed, the previous volume of 100 c. c. re-established and then 6 c. c. were taken for estimation of albumose peptone in the centrifuge, and 10 c. c. were subjected to the determination of nitrogen by Kjeldahl. In each case, from the amount of nitrogen determined, there was calculated the amount of albumose peptone, using 12 per cent. as the factor. A comparison of these two methods of calculation can be seen in the following table:

TABLE II.

	Pepsin.				Vegetable Digestant.			
Amount of HCl. Per 1,000.	Nitrogen in 10 c. c.	Reading Tube.	Estimated Albumose Peptone. Per cent.	Calculated from Nitrogen. Per cent.	Nitrogen in 10 c. c.	Reading Tube.	Estimated Albumose Peptone. Per cent.	Calculated from Nitrogen. Per cent.
2.5	.00126	.3	.1	.107	0	0	0	0
2.25	Miscar.	.3	.1	0	0	0	0	0
2	.0062	1.5	.5	.51	.0021	.45	.15	.18
1.75	.0044	1.25	.41	.37	.0036	.35	.28	.22
1.5	.0062	1.9	.6	.52	0	.15	.05	0
1.25	.0061	1.75	.58	.51	.0025	.7	.23	.21
1	.0056	1.35	.45	.46	.0030	.8	.26	.25
.75	.0067	1 86	.62	.56	.0032	.85	.28	.27
.5	.0054	1.3	.43	.45	.0023	.53	.17	.19
.25	.0043	1.15	.38	.36	.0026	.46	.15	.21

It is found upon comparison of this table that the percentage of albumose peptone calculated from the nitrogen, which is presumably fairly correct, compares very favorably with the amount which is estimated from the centrifuge precipitation. As the variation is not always in one direction, it is safe to consider that it is due to slight inaccuracies in calculation, and not necessary to the process.

Another noticeable thing about these digestions is, that the strength of HCl is apparently of lesser importance, provided only that all the albumin is saturated and that there is a slight excess. Every digestion except the last shows the presence of free HCl, and a marked difference can be seen between these results of digestion where a solution of .5 per 1,000 and .25 per 1,000 were used, to the great disadvantage of the latter. The presence of free HCl or the amount of free HCl has no significance whatever, beyond the fact that all the albumin present is converted to acid albumin. Hence we can see that the digestive power of gastric juice is dependent upon two factors, pepsin and HCl, and there is no reason why the power of both should not be determined as a whole, and termed the digestive power of gastric juice. In the absence of free acid, we are not yet clear that digestion may not occur, though to a limited extent. This point is now being investigated with favorable results.

Another thing which attracts our attention is the amount of albumose peptone which can be obtained from a stated quantity of native albumin. In these experiments, in our most favorable digestion 92 per cent. of the albumin was converted into albumose peptone. Whether the pepsin, which in every case was

20 per cent. of the albumin, was utilized to its fullest extent, we do not know; probably not. Yet it arouses an interesting discussion with reference to the use of pepsin as a therapeutic agent. At the same ratio, it would require 20 grammes of pepsin to digest the 100 grammes of albumin which are found in the ordinary individual's daily diet, if he is allowed to choose freely. All digestions in the laboratory are very much hindered by the products of their own digestive agent, a restriction which in the stomach is undoubtedly remedied by the constant absorption of these products, and in this case, pepsin would have a much wider range of efficacy than when its powers are so restricted. It is very improbable that albumose peptone alone is poured into the intestines, leaving the less fully digested products in the stomach, and the more reasonable belief is, that it is constantly absorbed during the process of digestion.

Experiment 3. — In order to test the process still further, certain digestions with pancreatin in an alkaline solution of varying strength, namely, from 1 to 5 parts per 1,000, were carried out, and the resulting products estimated. A control digestion in each case was also made with the vegetable enzyme which had been previously compared with the pepsin. The process of separation of the undigested products differed here, of course, from that previously used. It was found necessary to separate the alkaline albumin, plus the soluble albumin, by neutralizing with acetic acid, and to cook it, by which both substances were removed. In other respects, the digestions were exactly alike, the same amount of pancreatin and albumin being used as before. The results of the digestions were tabulated also, and can be seen as follows:

TABLE III.

	Pancreatin.				Vegetable Digestant.			
Strength Na_2CO_3 Per 1,000.	Nitrogen in 10 c. c.	Reading Tube.	Estimated Albumose Peptone. Per cent.	Calculated from Nitrogen. Per cent.	Nitrogen in 10 c. c.	Reading Tube.	Estimated Albumose Peptone. Per cent.	Calculated from Nitrogen. Per cent.
1	.0364	.9	.3	.3	.00224	.65	.21	.19
2	.0017	.35	.11	.14	.0007	.15	.05	.06
3	.0028	.75	.25	.24	.0016	.4	.13	.13
4	.0028	.25	.08	.23	.0021	.28	.09	.17
5	.0016	.4	.13	.14	.0015	.2	.06	.12

The most noticeable thing about this series of estimations is the inefficiency of the pancreatin of trade to digest albumin. If we take, for instance, the most favorable of these digestions, we find that only 42 per cent. of the albumin was converted into albumose peptone, while with the pepsin-HCl digestion, 92 per cent. of the albumin was converted. This leads us to consider seriously the value of pancreatin as a therapeutic agent, especially when we know that apart from its evident inability to convert albumin, we consider also the effect of the HCl upon it in its passage through the stomach. Of course, we are not speaking now of freshly prepared extracts of pancreatin, which have a much greater activity than the dried powder which is commonly used. In fact, it seems from the experience of others, that freshly chopped pancreas in substance has a much more valuable effect when it is desired to influence to duodenal digestion.

From a clinical standpoint, we have now the application of this method to the actual investigation of the power of gastric contents, removed from the stomach, and we must also recognize the fact that the HCl is equally effective, whether existing in a free form, or combined with albumin; so that it seems only necessary to filter out the insoluble food particles, and to use the gastric juice directly for digestive experiments. There is still some question as to the advisability of adding HCl when no free acid is present, but in the following experiment the gastric juice was employed just as it was removed from the stomach after filtration. There may be ample HCl for perfect digestion and still not a particle of it may exist in a free state. Combined HCl has not lost its power, with the aid of pepsin, of converting unchanged albumin to peptone. We may regard the term "digestive power" as the quality which gastric juice possesses of converting albumin to albumose peptone. It is always necessary to have a control which shall contain gastric juice alone, without the addition of albumin.

The process of Hammerschlag[1] is as follows: To add to a 4–1,000 solution of HCl albumin until we have a 1-per-cent. solution of this substance. Of this, measure out two portions of 10 c. c. each. To one add .5 c. c. filtered stomach contents; to the other, 5 c. c. water. Place both portions in a brood oven for one hour, and then estimate the amount of albumin in both by Esbach's albuminometer. The difference represents the amount digested, which can be calculated in percentage. In regard to this method it can only be said that the picric acid which Esbach's solution contained will precipitate albumose peptone as well as acid albumin, and hence the resulting difference is not necessarily due to the amount of albumose peptone formed. Our own applied method, which seems most satisfactory, is as follows: 10 c. c. of filtered gastric contents, either undiluted or diluted according to a definite proportion, are measured out and placed in a test tube, to which, afterward, .1 gramme of albumin is added, and it is allowed to digest for twenty-four hours in a brood oven or in a warm place. In another tube 10 c. c. of gastric contents, prepared in the same way, but without albumin, are placed in the same place for the same time. After this period, if no free acid is present, two or three drops of HCl are added, the solution is boiled in a test tube, and sodium carbonate added until no further precipitate is formed. These solutions are now filtered into two graduated tubes respectively, until six c. c. of each are obtained. Phosphotungstic acid and HCl are then added, as before, the whole is submitted to the action of centrifuge, and the difference in the reading of the two tubes divided by 300 will give the percentage of albumose peptone formed by the action of the gastric juice. This can be reckoned for 10 c. c., or can be reckoned as so many parts per 1,000. This method, employed in five cases, which comprise anacidity, subacidity and hyperacidity, gave the following results:

CASE I. Anacidity, with mild epileptic attacks. The gastric contents, removed one hour after a test meal, showed a tube reading of 1.4; with albumin, 3.3. The difference, 1.9, shows that 6.3 parts per

[1] Versammlung Deutscher Naturforscher und Aerzte, Wien, 1894.

1,000 were digested by the gastric juice. Fourteen days later another test made upon the same patient, who in the meantime had taken HCl, showed a tube reading of 1.3; with albumin, 4.4. The difference of 3.1 shows 10.1 parts per 1,000 digested.

Case II. Hyperacidity, with some dilatation, under the same conditions showed a tube reading of 3.9; with albumin, 5. The difference, 1.1, shows a digestive power of 3.6 per 1,000.

Case III. Deficient motility. Reading of the tube with albumin, 8 (3 c. c. used and calculated for 6 c. c.); without albumin, reading, 7. Difference, 1 c. c., shows digestive power of 3.3 parts per 1,000.

Case IV. Subacidity of neurotic origin. Reading of tube without albumin, 1.4; with albumin, 1.7; difference, .3. As the gastric contents were diluted with an equal amount of water, this factor must be multiplied by two, and equals .6 c. c., which gives a digestive power of 2 parts per 1,000.

Upon an examination of these results, one must be struck with the varying amounts of albumose peptone found in the pure gastric contents, and the question arises whether this cannot be a measure of the absorptive power of the stomach. We have excellent authority for this supposition. H. Tappeiner[3] and J. Brandl[4] both declare that not only albumose peptone but also acid albumin, and possibly soluble albumin, are absorbed in the stomach.

These results have been further substantiated by experiments performed upon persons suffering from almost complete closure of the pyloric orifice by malignant disease, in which solutions of albumose peptone of known strength taken into the stomach and after intervals of two to three hours removed by siphonage, showed a loss that could only be accounted for by their absorption in the stomach.

Furthermore, Riegel[5] states: "One can obtain an idea of the degree of the disturbance of absorption in the stomach by examination of the digestive products present in the stomach contents removed." In addition to this there appears to be a very unsatisfactory method extant of determining absorption. The method of Penzoldt and Faber,[6] which consists of ingestion of iodide of potash in capsules, has proved very unsatisfactory, and Boas[6] says: "According to my view, the time of elimination of iodide of potash is in no way a test of the absorptive ability of the stomach." Hence we are compelled to return to the question of the residual albumose peptone in the removed stomach contents as a possible measure of the absorptive power. This seems the more probable as it is incredible that only albumose peptone is poured into the intestine, and the less well-digested products remain in the stomach for further action. When, however, we find a large residual albumose peptone in the stomach, it may be due to faulty absorption or an unusually great activity of the digestive fluid present But, in general, it seems reasonable to consider the following statement as justified: The less the percentage of albumose peptone present, the greater the absorptive power of the stomach; and, vice versa, the greater the percentage, the less the absorptive power of the stomach. If, then, we regard this albumose peptone present as a measure of absorption, the digestive power of the gastric juice as a measure of its strength and activity, and the amount of gastric contents removed as a measure of motility, we have three factors which give us a fairly clear idea of the condition of the stomach. In order to get a clear idea of the correlative relation between these factors we will arrange the results of these five cases in a table, which reads as follows:

[3] Ueber Resorption im Magen, Zeitschr. für Biologie, vol. xvi, 1880, p. 497.
[4] Ueber Resorption und Secretion im Magen, Zeitschr. für Biologie, vol. xi, 1892, p. 277.
[5] Magenkrankheiten, 1897, p. 100.
[6] Berlin. klinische Wochensch., 1882.
[6] Magenkrankheiten, 1897, p. 215.

TABLE IV.

Nature of Case.	Amount Albumose Peptone. Per 1,000.	Digestive Power. Per 1,000.	Amount Removed.
Anacidity. First analysis.	4.6	6.3	128 c. c.
Second analysis.	6.3	10.1	105 "
Deficient motility.	13	3.6	135 "
Deficient motility.	23	3.3	100 "
Subacidity.	4.6	2	56 "
Gastric neurosis.	4	3.2	46 "

Upon looking at the above table we find these peculiar combinations: We may have good absorption, good digestive power and deficient motility, or we may have another combination of poor absorption, fair digestive power and deficient motility. These three factors once determined, in connection with the determination of the amount of rennin, make up an analysis which apparently affords us about all that chemical examination offers in the analysis of the stomach contents.

While it is possible that further examination and a larger number of cases may disprove these suggestions presented, yet it seems worth while to carry out this line of work until the truth or falsity of its deductions is proved. While chemistry can never completely supplant the means of physical examination presented to us, yet it must always form a powerful adjunct in the diagnosis of stomach disease.

Clinical Department.

NOTES FROM THE NEUROLOGICAL DEPARTMENT OF THE MASSACHUSETTS GENERAL HOSPITAL.

II. Two Cases of Thompsen's Disease, and One of Transient Myotone, Occurring in One Family.

BY S. A. LORD, M.D., BOSTON.

Case I. Howard J. G., an American of eighteen, came to the clinic on December 16, 1899, during the service of Dr. Walton, complaining of difficulty in opening the clenched hand, "crackling" in the joints, "prickling" in the limbs at times, and occasional numbness of the fingers and toes (but only when they became cold). He was "sickly" up to the age of nine, after which he became strong and athletic above the average (so he states), and lived as a farmer. When about twelve years old he began to notice a stiffening of the thigh muscles immediately after starting to climb upstairs, rendering him almost powerless to advance for several moments; this would then slowly lessen, full freedom and power of motion returning when two or three additional steps had been taken. The trouble grew more severe, so that in less than a year after the onset any considerable jar suf-

ficed to make his legs rigid in an instant. Finally he refused to go to school, on account of the ridicule to which he was subjected. It then became hard to open the hand after a firm squeeze (eighteen months after the onset). The tendency growing still more marked, every time he "stubbed" his toe he fell to the ground, all voluntary motion of the neck, body and limbs being temporarily abolished by tonic spasm; and, at the present time, the general rigidity is so complete on such occasions that a half minute often elapses before the patient can arise. He can always move the tongue and face muscles during these spasms. Except as a part of such universal rigidity he never perceives involvement of the erector spinæ, the motions of stooping and rising being quite free After a sneeze, it is said, he cannot straighten up for a few moments, on account of the abdominal spasm. Involvement of the pectoralis, trapezius, latissimus dorsi, or deltoid is not often marked enough to inconvenience him. He states that jaw movements are occasionally difficult, especially when he has been exposed to cold; and the same is true of the tongue. In the legs the impeded thigh movements annoy him more than anything else, but the muscles below also are not spared, the flexor spasm of the toes resembling that of the fingers.

The rigidity is described as transient, not returning as long as action is kept up. The patient "could chop wood all day" if no variation in the motion were attempted. Likewise he can walk indefinitely when once over the initial disability, and states that he can run upstairs provided that some preliminary "dancing" is indulged in, and that there is never the slightest hesitation in going downstairs. He is confident that fear has no effect. Provided that he does not *sweat*, the whole tendency decreases on hot days; sweating exerts a marked influence for the bad, according to him, as does exposure to cold. He thinks that hard work makes the trouble worse, unless he can keep from perspiring. Effort to overcome the spasm is not only almost entirely ineffectual and very painful, but, in addition, is said to prolong distinctly its duration. Damp weather increases it. There has been no opportunity to judge of the effect of alcohol.

The disorder steadily increases in severity. This has been made especially evident recently in connection with the milking of cows, which can now be accomplished only after fifteen minutes' practice. He has, in fact, been inefficient in all employments essayed of late. He states that notwithstanding this progression of the disease, his muscles are becoming stronger as well as larger, and that he is still growing. There has been noticed during the past year a marked tendency to nose-bleed. The general health is excellent, and the mental and vital development normal, puberty having been reached at fourteen and the sexual power being adequate. The patient is temperate and of good habits.

Family history. — This is incomplete on the maternal side, but is said to be in general good. No instances of myotonia except the three here discussed are known in the family.

Status. — The patient is below medium height; he is well nourished, with slightly developed panniculus adiposus and remarkably developed muscles, those in the legs being strikingly large. The thigh measures 21½ inches (54 centimetres) and the calf 15½ inches (40 centimetres). Over the scrotum and penis there is a condition of vitiligo, but the organs are well developed. The maximum impulse is in the fourth space, and the pulse (patient standing) 106 (it is to be regretted that the constancy of this rapid rate was not confirmed); the sounds and boundaries are normal. The thyroid gland is present, of normal size. Hearing and eyesight are good. Slight ulcerations are found on the septum, accounting for the nose-bleed, and there is a small adenoid. Cover-slips of the blood showed nothing abnormal, either in the character of the reds or in the differential white count. The red count was unfortunately inaccurate, but it seems almost certain that there was no deficiency in number. There was an apparent plethora. The urine is of normal appearance and specific gravity and contains no albumin or sugar.

Sensation. — Everywhere normal, unless the remarkable intolerance of the skin to painful and (less decidedly) to tactile stimuli be deemed hyperesthesia; there was no examination of visual fields or fundus. On palpation, the muscles are found to be abnormally firm, especially those of the legs. There is slight, fine tremor of the hands; no fibrillation or inco-ordination. The muscle bellies are of the short type.

Reflexes. — The pupils are normal. The knee-jerk is difficult to obtain; with re-enforcement it is present in normal degree, but shows tendency to weaken after three or four repetitions. The observations as to whether it was completely abolished on repetition were somewhat contradictory on different occasions; this is not surprising, considering the well-known variations in degree which the symptoms present in the individual case of myotonia. It happened at least once that I was unable to obtain the knee-jerk after several responses, successively lessening in vigor, had been excited. Local myotatic irritability may still be observed during the (only apparent?) absence of knee-jerk. The Achilles phenomenon presents a contrast: repetition certainly does not weaken it and it is easily obtained. There is no ankle clonus or triceps- or wrist-jerk. The front-tap contraction is present. The cremasteric, abdominal and plantar reflexes are normal.

Voluntary motion. — The gait and leg movements in general are somewhat slow. Two or three trials in quick succession did not enable the patient to run rapidly upstairs, even after the initial spasm had passed away. This residual awkwardness is probably pathological, and is accounted for perhaps by the fact that in this patient the subsidence of myotonic rigidity is not at once perfect, that after cessation of the evident spasm some further improvement in functional ability goes on, perhaps also in part by the abnormal consistency of the hypertrophied muscles. The muscular strength is poor compared to the development, but there is no evidence that the muscles tire quickly. Motions of the face, lips, eyes, eyelids, pharynx and larynx are absolutely normal, and there is no hindrance to the actions of spinal flexion and extension or to respiration. When the jaws are closed tightly the masseters become very firm and prominent and remain so for several moments after attempt is made to relax. Lateral but not forward movements of the jaws also result in after-spasm. The action of the genioglossus in the motions of the tongue is perfect, but the intrinsic muscles work slowly for an instant when an attempt is made to curl the tongue

backward or to execute lateral movements rapidly. The disorder is well marked in the neck muscles; on forced rotation the neck becomes set in that position for a time. In anteroposterior action the spasm appears after two or three oscillations, the head then becoming fixed; on lateral flexion the spasm is not so marked. The trapezius and other shoulder girdle muscles and those of the upper arm all present the characteristic tonic after-contraction; it is extremely pronounced in the biceps, triceps and in the flexor group of the forearm. On shutting the hand tightly it can be opened only with the greatest effort and slowness, and there is a high degree of resistance to passive extension; not so great, however, but that it can be overcome. Ordinary hand movements are free after two or three voluntary openings and closings. Severer tests, requiring much continued effort (as in the action of milking, already alluded to), would probably make it evident that a certain amount of impediment to motion persists several minutes; this statement seems justified in view of the positive testimony of the patient as to the protracted difficulty now experienced in milking cows. The gradual betterment of his walking power during the first mile or two bears equal significance, and is mentioned here to emphasize this point. The extensors of the fingers, contrasting sharply with the flexors, show a remarkable exemption from spasm — apparently complete — for the open hand can always be closed with instant readiness, The wrist, again, is involved both in extension and flexion. The small hand muscles are also involved in some motions, but writing, though labored, causes no spasm. There is momentary after-spasm of the abdomen on coughing. Lateral and rotatory trunk movements are similarly affected. The thigh muscles become rigid with the attempt to sit down on a chair twice or thrice rapidly, the patient being finally left standing, unable to bend his stiff legs. Adduction of the thighs is involved, but abduction shows an apparent exemption. The toes, like the fingers, can always be flexed at will, but extension is slow and difficult. The spasm is most intense, prompt and prolonged in the forearm and thigh. An attempt to go briskly upstairs is arrested on the third or fourth step, but not absolutely. progress being possible, though barely perceptible, throughout the duration of the spasm. The degree of rigidity in the legs is brought sharply to notice by the loud snapping of knee tendons during relaxation of the spasms. On placing the phonendoscope upon the joints in action, vibrations of seemingly abnormal intensity are heard.

With regard to voluntary movement after rest, then, rigidity is seen never to manifest itself till the intended contraction, with its entailed single motion, has been performed If, now, that contraction has been extreme, if the effort is intense, the muscle will not relax despite the pulling of antagonists. Spasm does not therefore occur strictly at the *beginning* of intended movement. With less vigorous effort the spasm is less marked, and its development is not abrupt, one or two relaxations and contractions being possible before motion is suspended. The rigidity at its maximum does not utterly abolish motion. It is not seen to last more than eight seconds, begins to decrease with the third, and has disappeared with the fourth movement. Attention exercises no visible influence. Prolongation of the resting time has distinct influence in intensifying the next spasm. To ensure the appearance of spasm at resumption of motion a rest of at least sixty seconds is necessary if the muscles have been brought to a freely working state. The rapid cessation of spasm observed during the third and fourth movements seems to be followed by further improvement in muscular control, which is mostly subjective and extends over fifteen minutes or more if action continues. The immediate cause of impeded motion is the failure of the muscle, once contracted, to relax; involvement of the antagonists is seen as an augmenting factor, but this does not seem to be an element in the case of finger-and-toe movements, in which the singular immunity of the extensors results in the arrest of motion in flexion. The sudden generalized rigidity following a stumble, previously mentioned, doubtless has in its direct production the elements both of mechanical excitation and of intense effort.

Mechanical irritability of the muscles. — This is exaggerated in a way absolutely typical of congenital myotonia. The facial muscles and the masseters do not show the reaction. In general, a fairly sharp blow is needed to bring it forth. On striking the deltoid, the whole muscle becomes rigid, the rigidity being greatest at the point struck, with the production there of a deep furrow, lasting several seconds. It is less easily produced in the forearm muscles. I could not obtain it in the erector-spinæ mass. It is very marked in the thigh; here a quick blow with the fist causes a prolonged tonic spasm of the whole extensor group, the separate bellies standing out prominently. Well-defined furrows can be called forth by brisk strokes with small instruments; the vastus externus is especially susceptible. The same phenomena may be observed in all the groups of leg muscles. No idiomuscular mound was seen, and a trial to obtain the contraction by pressure was unsuccessful. The persistance of this irritability during apparent absence of knee-jerk has been mentioned. Attempt to elicit the "paradoxical contraction" by dorsal foot-flexion was without success. The *nerves* do not show increased mechanical excitability (facial, peroneal).

Myotonic electrical reactions. — These were studied in the deltoid, the arm and forearm and thigh muscles; those of the face reacted normally to both currents. Faradism: The muscles react to weak currents, which call forth momentary contractions when momentarily applied, tetanic after-spasm when the stimulation is longer. A deep furrow lasting nearly ten seconds after slightly prolonged stimulation can be produced with a very weak current. Galvanism: Weak currents act like the faradic. Tetanic after-spasm is seen in the quadriceps with five milliampères, both poles; the spasm slowly disappears and successive shocks lose their efficacy, there being finally no response. If the poles are then reversed the contraction again appears. No rhythmical contraction could be demonstrated; the strength and duration of current found requisite by other observers could not be borne by this patient. Commonly it is impossible to obtain opening contractions in this disease, but they were twice seen in this case, in the quadriceps at the anode. With a strength of ten milliampères a remarkable pulsating contraction, not exactly rhythmical, and showing no appreciable polar relation, was observed in the same muscle. The relations of the poles are apparently not entirely constant; in the quadriceps CaClC > AnClC and CaClC < AnClC were both noticed. In the deltoid, however, the anodal contrac-

tions are constantly greater than the cathodal. *The reaction of the nerves* to electricity is normal to both currents. Labile galvanic stimulation, mentioned by Oppenheim in his text-book as giving rise to myotonic reaction, was not tried.

CASE II. Brother of Howard G.; is a clinical counterpart if the descriptions are correct. This person lives in a distant State, and I have not seen him. He is two years older than H.; the symptoms came on at the same time of life — two years before puberty — and are of like severity. He is said to be subject to occasional attacks, in which there is complete loss of consciousness along with myotonic condition of body and limbs (resembling that of H. after stumbling), thus presenting the not infrequent combination (Oppenheim) of Thompsen's disease with epilepsy, in all probability. It is to be understood that myotonia exists in typical form in the intervals.

CASE III. Cordelia G., age twenty-three, single, sister of Howard G.; is well and strong except that for a week before each catamenial period she experiences a peculiar momentary motor incapacity of the legs on going upstairs, after taking two or three steps; it never amounts to anything like total arrest of power, but is well marked. This gradually increases as the period approaches, but disappears wholly when the flow begins. There is also some difficulty in arising from a squatting posture at such times. Nothing but true myotonic affection, in very slight degree, seems to explain these symptoms. The hands and arms are not affected, nor any other muscles, according to the patient's knowledge. The trouble came on at sixteen. This woman I saw personally, but have not seen the manifestations she describes. They are best termed "transient myotone," but the propensity is probably congenital.

In the other cases the diagnosis — Thompsen's disease — cannot be questioned; and though the name myotonia congenita has not its usual applicability here, inasmuch as the affection did not appear in infancy, it is more suitable than that of myotonia *acquisata*, because the symptoms are otherwise typical of the congenital form and because the family tendency is pronounced; such late onset is uncommon in the family type, but has been observed. Myotonia may indeed have existed unnoticed in early childhood.

In the literature are many atypical cases and numerous instances of associated conditions, of which two — progressive muscular dystrophy and paramyotonia congenita — deserve mention here, for in the case of Howard G. there is a resemblance to dystrophy in the weak, short-bellied and hypertrophied muscles, which present further an abnormally firm (though not lumpy) consistence; a likeness to paramyotonia on the other hand is seen in the influence of cold on the actions of the tongue and jaw muscles.

Worthy of recapitulation are the following points of particular interest: (1) The unusually late onset; (2) the continued progression of the disease; (3) the brief duration of the after-spasm — considering that the occasional occurrence of almost universal rigidity indicates a severe form of the affection; (4) the protracted persistence of a slight amount of spasm, usually in this case not evident except subjectively as a feeling of awkwardness; (5) the exemption of the erector spinæ and of the finger and toe extensors from spasm; (6) the diminished knee-jerks and their tendency to disappear; (7) the final absence of response to electric shocks after repetition, and (8) the reappearance of the response if the poles are reversed; (9) the presence of opening contractions, and (10) the absolute periodicity of the myotonic symptoms in the sister, this condition not having been previously reported so far as I know.

These cases present nothing new concerning the most interesting question in connection with myotonia — its etiology. The remarkable periodicity observed in the case of the sister seems to indicate merely either that wholly new conditions exist in the organism at the catamenial time, sufficient to bring about a myotonic state, or that a constant latent tendency is aggravated into evidence by the disturbance of vital equilibrium common at the menstrual period. Of the immediate or ultimate causes of myotonic spasm we have no knowledge. The much-divided opinion as to the direct cause has perhaps favored a muscular origin, while there are still adherents of the auto-intoxication theories. The classic muscle-fibre appearances have now a doubtful significance, however, particularly since Jacoby showed that they may arise through faulty technique.

It will always be difficult to rule out the participation of either one of the structural elements concerned, the nervous and the muscular, on account of their intimate and inseparable connection in function. But it is permissible to remark that, regarding the immediate, direct cause of the spasm, more will probably be heard of *inhibition* than heretofore, in view of the great importance now attached to it in the minds of physiologists, as a normal and constant element in all vital phenomena. If these phenomena are but resultants of the antagonistic actions of the two nervous forces, acting always concomitantly, of which inhibition is one, then we may reasonably regard myotonic spasm as the result of defective inhibitory supply. This would express only the immediate cause of the spasm, for those subtle influences determining the quantity and distribution of inhibitory impulses — in this conception the ultimate causes of the spasm — are of course unknown to us in our absolute ignorance of the nature of inhibition itself. Such a supposition is apparently as plausible as others put forth, and offers the further advantage of allowing an expression of the facts (in part imperfectly, it must be acknowledged) in terms of a physiological process, of simply a loss of balance between the opposing forces in the delicately adjusted nervous system. As Schultze has recently remarked, however, it is hardly profitable to speculate at length concerning the etiology of this disease so long as our knowledge of the physiology of muscular contraction remains far from complete. And Bernhardt, still more recently, in reporting a unique case combining the symptoms of atypical Thompsen's disease with those of paramyotonia and atrophy (questionably neuritic), comments upon the possible importance of the relation of myotonia congenita to those and other diseases, and urges an exhaustive review of the subject of etiology, with a complete recasting of our ideas as to it from the point of view of such relation.

Medical Progress.

REPORT ON PROGRESS IN PATHOLOGY.

BY JAMES H. WRIGHT, M.D., BOSTON,
Director of the Laboratory of the Massachusetts General Hospital.

MALARIA AND MOSQUITOES.

In a paper read before the Tenth Congress of the Societá Italiana di Medicina Interna, Bastianelli and Bignami [1] sum up the results of their observations on the transmission of malarial infection by mosquitoes. They have experimented with all three forms of malaria: the estivo-autumnal, the tertian and the quartan. With the co-operation of Grassi, a zoölogist, they think they have demonstrated that the only kinds of mosquitoes that are concerned in the transmission of the disease are various species of the genus anopheles. These are found only in malarial districts. The parasite peculiar to each form of malarial fever has two life cycles, one completed in man and the other begun in man and completed in the mosquito. The cycle carried out in man is the one already long known, which is characterized by the breaking up, or the segmentation, of the adult parasite into a number of young parasites. The other cycle is represented in the estivo-autumnal fever by the "crescents," and in the other fevers by certain forms of the parasite which the authors do not clearly describe. These forms are regarded as sexual forms, and the authors seem to think that they are incapable of producing themselves in man. When they are taken into the stomach of the mosquito, however, they go through a special life cycle lasting ten or twenty days or more, as follows: Some of them develop into the well-known "flagellate bodies," and some develop into peculiar round bodies without flagella. Next, the flagella detach themselves from the "flagellate bodies" and one of the flagella penetrates a round body to impregnate it. The round bodies so impregnated then undergo certain changes and make their way into the wall of the intestine. Here they increase in size, and acquire each a delicate enveloping membrane, and segment into a great number of smaller bodies. The latter then elongate themselves and assume a filiform appearance. Later the enveloping membrane ruptures and the filiform bodies are disseminated throughout the body of the mosquito and eventually accumulate in the cells of the salivary glands, whence they are discharged into the blood of man. The authors found difficulty in infecting the mosquitoes with quartan parasites, although they did succeed in doing so. They explain this on the ground that the quartan parasite probably develops in man only a few sexual forms that are capable of undergoing further development in the mosquito.

These interesting results of these Italian observers are the direct outcome of the brilliant work of Major Ross, done a few years ago, who showed that in the stomach of mosquitoes fed on the blood of malarial patients the crescentic parasites develop into the flagellated forms and liberate their flagella. He also showed that a certain parasite, very similar to the malarial parasite found in the blood of birds, underwent a peculiar cycle of development in the body of the mosquito and that such infected mosquitoes were capable of infecting healthy birds by their bites.

The observation by MacCullom that the flagella of the flagellated bodies behave like male reproductive elements has also contributed not a little to the development of our knowledge of this subject.

According to Bastianelli and Bignami, the crescentic bodies found in the blood in the estivo-autumnal fever originate principally in the bone marrow, where many young forms are to be found.

They state that a single mosquito may infect an individual, and in fact, several individuals, for they have found numerous parasites in the salivary glands of mosquitoes by whose bites they have experimentally produced malaria in healthy subjects. They have also made a study of the mosquitoes of very malarious districts in Italy, where almost the only genus is the anopheles. In the months of June and July only three per cent. of the mosquitoes examined were found infected with the parasites, while those caught far from any habitation were found free from malarial infection. They concluded from this that the few malarial infected mosquitoes met with here acquired the parasite from persons who were suffering from relapses of malaria. They also reported the following interesting observations: A number of harvesters were housed in a big granary. In this on June 23d, only one mosquito was found. On the 24th, eight mosquitoes were found, and on July 1st, 366. Of these 90 were examined and only three were found to be infected, but subsequently the number of the infected mosquitoes rapidly increased. At another place 42 laborers were housed in huts on an estate. On July 2d, out of seven mosquitoes only two were found infected. On July 17th, 15 mosquitoes out of 32 were found infected, and on July 20th, 11 mosquitoes among 17 contained the malarial parasites. Mosquitoes captured during the same period in the stables of the estate or at a distance were found free from infection as a rule. At the end of July or early part of August, nearly all of the men who had lived in the huts during this period had become affected with malaria.

As regards the prevention or limitation of the spread of the disease, the authors emphasize the necessity of getting rid of stagnant water and also the necessity of administering quinine early in the disease, for thus not only is the danger of relapse diminished, but the development of the parasites into those forms that complete their life history in the mosquito is prevented or interfered with. They think that malaria should be regarded by the authorities as an epidemic or contagious disease and treated accordingly.

PIGMENTATION IN ADDISON'S DISEASE.

The mechanism of the pigmentation in Addison's disease has been studied by only a few observers. According to Nothnagel, the pigment is carried from the blood to the epithelial cells of the skin by means of "wandering cells." The pigment was also found by Nothnagel about the vessels of the skin and in their walls.

Riehl found hemorrhages about the vessels of the cutis and in the neighborhood of these hemorrhages brown-colored "cutis" cells. Many of the vessels were thrombosed. According to Riehl, the cutis cells derived their pigment from extravasated red blood corpuscles.

Von Kahlden could not confirm the observations of Riehl. He found in the case of the tongue that the pigment was contained chiefly in the cells of the papillæ and not in the epithelium. In the subpapillary

layer amorphous black pigment was often present in the form of granules and clumps and outside of cells. He also found in some vessels black pigment granules among the red corpuscles.

Pförringer,[3] in a recent article, reports the results of his study of this subject. The case was a typical one, there being extensive tuberculosis of the adrenals. He could find no microscopic changes which seemed to him significant, neither in the splanchnic, nor in the sympathetic nerves, nor in the semilunar ganglion. The microscopic examination of the pigmented skin showed, in the tissue of the cutis, pigment in clumps, and, in the vessels of the part, pigment in granules, free or enclosed in blood corpuscles. The author thinks that the pigment in this disease comes from the blood, leaving the capillaries as granules either free or enclosed in leucocytes. He does not deny that the "wandering cells" may play a part in carrying this pigment, but he thinks that some of it gets into the epithelium directly from the vessels, which in many instances lie very close to the lowest layers of the epidermis. Upon the primary origin of the pigment he has no definite opinion.

A CASE OF HEMOCHROMATOSIS.

E. L. Opie[3] reports a case of typhoid fever with pigmentation of the skin and various organs, notably the liver, pancreas, heart and gastro-intestinal tract. There was also cirrhosis of the liver and chronic interstitial pancreatitis. Microscopical examination showed an abundant deposit of pigment throughout the liver tissue. This pigment gave the microchemical reactions characteristic of iron. In addition to this pigment a second form was present which gave no iron reaction. It was in the form of small granules in the smooth muscle cells of the blood-vessels and in their connective-tissue sheaths. Both forms of pigment were also present in the pancreas. In the heart, the iron containing pigment was found in large amount in the muscle cells. In the gastro-intestinal tract, both forms of pigment were present, the iron-free form predominating. It was situated in the smooth muscles and in the connective-tissue cells. There was a less degree of pigmentation of other organs.

In the liver, necrosis of the liver cells was frequently observed in association with the pigment accumulation. The author seems to think that the necrosis and the interstitial increase in the pancreas are the results of the cell death, brought about by the pigment deposits. He regards the iron containing pigment as derived from the hemoglobin of the blood, which is set free by breaking off the red blood corpuscles. He calls attention to the fact that in all cases of so-called bronzed diabetes there has been found a chronic inflammation of the pancreas. The diabetes in these cases seems to be a result of the chronic inflammation of the pancreas and to be a terminal event in a disease characterized by general pigmentation. In Opie's opinion, the interstitial changes in the pancreas are the result of necrosis of the pancreatic cells, produced by the deposition of the iron pigment. In this view bronzed diabetes would be a disease which is due primarily to a destruction of the red blood corpuscles. As Welch has pointed out, however, in his discussion of Dr. Opie's paper, it seems that this explanation of the disease is inadequate, for a number of conditions are known in which there is much destruction of red blood corpuscles without the production of pigment deposits like those in the present case.

THE GONOCOCCUS IN ACUTE DIFFUSE PERITONITIS.

Cushing[4] reports finding gonococci in the peritoneal exudate in two cases of diffuse acute peritonitis secondary to salpingitis. The gonococci were found in cover-glass examination in both cases, and in one of the cases they were isolated in cultures as well. They were not present in the uterus or in the vagina, but were found in the inflamed Fallopian tubes.

These cases are worthy of mention, because notwithstanding the widely accepted view that cases of peritonitis due to the gonococcus are not uncommon, the only other case of acute peritonitis that we know of in which gonococci were satisfactorily demonstrated is the one reported by Wertheim in 1882.

HISTOGENESIS OF PERITONEAL ADHESIONS.

Büttner[5] has studied the process of organization of the fibrinous peritoneal exudates. He finds that the first step in the process is the proliferation of the connective-tissue cells beneath the flat pavement cells of the peritoneum. These connective-tissue cells had begun to proliferate by the end of the second day. They elongated themselves and grew into the exudate into which they had penetrated far after five days, when newly formed blood-vessels derived from the adjacent vessels of the part also made their appearance. The flat cells of the peritoneum in the affected region were not actively concerned in the process of the organization. They became swollen, were loosened from their attachments, and after three and one-half days only fragments of them were to be found.

BACTERIA IN TYPHUS FEVER.

Balfour and Porter[6] have made cultures from the circulating blood in 43 cases of typhus fever. In 36 out of the 43 a diplococcus was found. This organism appears from their descriptions to have considerable resemblance to some of the cocci which normally inhabit the skin. The blood for examination was obtained from the thumb of the patient in every case, the skin being thoroughly disinfected beforehand. The cultures were made by mixing the blood so obtained with bouillon. No growth was obtained from blood placed on solid culture media, but the organism, after growing in bouillon, grew readily on the ordinary solid culture media. The authors seem to have fully appreciated the likelihood of results obtained with such methods being open to serious criticism, and that it would be hard to convince bacteriologists that the organism they obtained was not an inhabitant of the skin. With the idea of meeting such criticism they report a number of examinations of control cases, among these being cases of measles, scarlet fever and typhoid fever. In 40 of 46 cases of typhoid fever the same diplococcus was found, but it was not encountered in any of the other cases.

Twelve cases of typhus were examined at autopsy. In eight out of these nine cases pure cultures of the diplococcus were obtained from one or other of the internal organs. Inoculation experiments with the

[5] Beiträge z. path. Anat. u. allgem. Path., Bd. xxv, S. 453, 1899.
[6] Edinburgh Medical Journal, December, 1899.

diplococcus on animals showed that it was pathogenic for rabbits by intravenous inoculation, producing a rapidly fatal septicemia. From the inoculation of guinea-pigs no positive results were obtained. In monkeys, while no fatal effect by subcutaneous inoculation was produced, yet some days after the inoculation, the diplococci were found in the circulating blood. A monkey intravenously inoculated gave a negative result.

While these observations are interesting and suggestive, they require confirmation before they will be generally accepted as of much value.

A CASE OF TRUE LYMPHOMA.

E. R. Le Count[7] reports his examination of a tumor of the groin the size of a pigeon's egg, which in microscopical structure was identical with a lymphatic gland, having the follicles and sinuses which are characteristic of these organs. Such a tumor as this seems to be of rare occurrence. Most of the tumors which are described as lymphomata do not repeat the structure of a lymphatic gland. This tumor must be regarded as an example of a true lymphoma. The author emphasizes the need of a thorough revision of the classification of tumors of lymphatic glands.

SCROFULOUS LYMPHADENITIS.

F. C. Moore[8] has tested the virulence of the tubercle bacilli in 26 cases of this condition. He found that the tubercle bacilli from these cases were clearly less virulent for animals than the bacilli from pulmonary phthisis. The author seems inclined to regard this diminution in violence as due to the natural resistance of the tissues of the lymphatic glands rather than to a primary low grade of virulence in the bacilli themselves.

A CASE OF BLASTOMYCETIC DERMATITIS.

L. Hektoen[9] reports a fifth case of blastomycetic dermatitis. The disease involved a considerable area on the right leg, and the dorsal aspect of a portion of the right thumb, wrist and forearm. The affected skin was reddish in color with thickening and induration; there were no pustules or vesicles. Microscopic examination showed essentially a chronic suppurative process with hyperlasia of the epidermis. The parasites appeared in microscopic preparations of the lesions as round or oval bodies provided with a homogeneous capsule. Their protoplasm was granular and sometimes contained a vacuole. The organism seemed to multiply by budding as does the yeast organism. The organism grew readily on the ordinary culture media, but beerwort agar was found best suited for its growth. Animal inoculations showed that the organism was pathogenic to rabbits, guinea-pigs, white rats and gray mice. In these animals its effects are chiefly local, producing necrosis, suppuration and granulation tissue formation. It also seems to produce a slow toxemia which in time may become fatal. A young dog, into whose jugular vein a suspension of the growth had been injected, died greatly emaciated within a few weeks. The autopsy and subsequent microscopic examination showed minute foci of granulation tissue scattered throughout the lungs, and focal lesions in the kidneys. The organism was recovered by cultures from the lungs and kidneys. This yeast-like organism is very much like the one described by Gilchrist and Stokes a few years ago, yet shows some cultural differences.

THE VITALITY OF THE BACILLUS OF THE PLAGUE.

Yokote[10] buried mice dead of the infection with the bacillus of plague in garden earth, and tested the dead bodies from time to time for the presence of the bacillus. He found that the bacilli survived in tissues of the dead animal for thirty days at the longest. They disappeared more quickly if the putrefactive process was active. The bodies were buried in wooden boxes, and it is interesting to note that in the earth of their vicinity none of the bacilli were found.

HYDROCEPHALUS AND HYPOPLASIA OF THE ADRENALS.

Czerny[11] has found imperfect development or absence of the medullary portion of the adrenals in five cases of hydrocephalus in children. Since no signs of degenerative changes were observed the author regards the condition in the adrenals as an anomaly of development. He has no adequate explanation to offer of this remarkable association of conditions.

THE EXPERIMENTAL PRODUCTION OF CANCER.

Lack[12] reports the results on experiments on rabbits in which the ovaries were incised and scraped with a knife, and the fluid which exuded allowed to spread over the peritoneum. One of the rabbits lived for nearly a year, when it became emaciated and was killed. At the autopsy numerous firm white nodules were found in the mesentery, pleura, lungs and uterus. There were also areas of firm tissue in the liver, together with many cystic formations. The nodules were found to exhibit the typical microscopical structure of carcinoma of the ovaries, consisting of columnar epithelium, arranged in alveolar spaces and of a connective-tissue stroma. In Lack's view, carcinoma is essentially an invasion of the lymph spaces by normal epithelium; once arrived in this space the cells continue to multiply. The frequent carcinosis of the peritoneum that follows the removal of cystomata of the ovaries is regarded by the author as the result, in some cases, of the escape of the free cells from the tumor into the peritoneal cavity. He does not believe that the occurrence of carcinosis of the peritoneum in these cases is necessarily a sign that the original neoplasm was of carcinomatous or malignant nature.

Reports of Societies.

THE OBSTETRICAL SOCIETY OF BOSTON.

MALCOLM STORER, M.D., SECRETARY.

Meeting of November 21, 1899, the President, Dr. Alfred Worcester, in the chair.

Dr. W. L. Burrage read a paper entitled

FURTHER EXPERIENCE WITH THE OPERATIVE TREATMENT OF RETROPOSITION WITH ANTEFLEXION.[1]

[1] See page 241 of the Journal.

DR. E. REYNOLDS: I would like to ask whether the uterus as a whole has a tendency to sag forward after the division of the posterior ligaments.

DR. BURRAGE: I have never noticed any such tendency, nor, on the other hand, do the divided ligaments tend to contract. A lozenge-shaped gap is left after the division of the ligaments over which the peritoneum is adjusted.

DR. C. H. NOBLE, of Philadelphia, by invitation, read a paper entitled

REMARKS UPON THE TECHNIQUE OF THE CLOSURE OF THE ABDOMINAL WOUND.[2]

DR. M. H. RICHARDSON: I have of course used at one time and another various methods to close the abdominal wall, but have never seen any reason to give up the through-and-through suture. I should not be willing to accept as an axiom that this suture is more liable to suppurate than any other. As to hernias, while I can give no figures, the number that have occurred in my practice must be extremely small, otherwise I would be apt to hear of more. Of course it is possible that other men sew up my hernias as I sometimes do theirs, but they would be apt to let me know. I always notify other surgeons when operating upon cases upon which they have worked previously. Of course in suppurating wounds the percentage of hernias is large, but I am surprised that it is not greater. While my number of wound infections, of course, cannot be smaller than the splendid showing of the reader, it certainly is very small indeed. In the first six months of this year in over 200 abdominal operations I can hardly remember a single wound infection, even in appendix operations. The last 260 intercurrent appendix cases all recovered without wound infection. The great disadvantage of the layer suture is that it leaves one or two dead spaces. I never saw a wound which might not become filled with blood. This is well shown in breast cases, where we are very careful to stop all oozing, yet it is common to see a hematoma. It seems to me that there is more liability for infection to take place where such dead spaces are present. In stout people I am apt to sew through and through and then sew up the aponeurosis separately. From 1886 to 1892 I used silver wire almost entirely. The great objection is that the buried ends are apt to irritate. Now I use nothing whatever but silk, and see no reason to abandon its use, and it certainly is excessively rare to have to take out a buried suture. I object to catgut because it does not bite; in tying a large artery with catgut it does not feel secure. I do not like to desert an approved method, and so I stick to silk.

As to disinfection, I think gloves are the greatest advance that has been made in surgery in late years. Previously we have seen every year one or two cases going to the bad inexplicably with general peritonitis. Now with gloves nothing of the kind occurs. In the last six months I have also used a gauze mask. I do not believe there is any very great danger of infecting a wound after a few hours. By that time it has become sealed up.

DR. J. G. BLAKE: In Alexander's operation my results have been satisfactory with interrupted sutures, followed by the dusting with iodoform or dermatol. In 60 or 70 cases I can hardly recall more than one or two of suppuration.

[2] See page 256 of the Journal.

DR. G. HAVEN: I have not been able to see very much difference as regards hernias or suppuration no matter which method was used.

DR. G. H. WASHBURN: I have seen very few hernias following the abdominal operation, and it has so happened that most of those few have followed the tier suture. Sometimes I use one method and sometimes the other.

DR. W. L. BURRAGE: I am absolutely in favor of the tier method. From theoretical reasons the abdominal wall must be stronger when we bring back the layers as nearly as possible as they were before operation. Dead spaces can be avoided by bringing the layers together by one or two deeper sutures. I use chlorinated lime and soda and rubber gloves. Instead of adhesive straps I put collodion on gauze around the wound. This stays on for a week. I think a woman is entitled to having her abdominal wall restored to its original state as nearly as possible if we have time enough to do so. Torri has shown the great advantage of the tier method, and also that the through-and-through method gives a potential hernia in many cases.

DR. E. REYNOLDS: For a number of years I have been studying this subject, and it is my custom always to try the strength of the abdominal wound from inside with my finger before closing. I think that theoretically the tier method has advantages in all abdominal incisions except in Cæsarean sections. Practically I have gone back to a modified through-and-through suture. In small wounds where there has been little manipulation, I do the layer suture. In long operations with a large incision, I have been surprised to see how much separation of the layers there always is and how hard it is to fill in the dead spaces. My method of closure is to catch the peritoneum together with fine silk and then do a through-and-through suture, picking up the muscle as I go, while at the lower angle of the wound I put one or two silkworm-gut sutures well below the cut, with especial reference to hernia, killing any dead space, for some years ago I noticed that all hernias start in the lower angle of the wound. The only trouble with the layer suture that I have found has been in the subcutaneous fat, especially in very fat women. I think gloves the greatest advance made for a long time. The man who always uses them is apt to have clean hands, and, furthermore, they enable us to do clean work soon after touching a septic case. Finally, I do not think we all appreciate the importance of slight septic infection in determining the result in critical cases. Since using gloves it seems to me that critical cases have done better than before. I agree with Dr. Richardson as to the importance of the face mask. I have seen a hair drop from the beard into the abdominal cavity.

DR. J. B. BLAKE asked as to the use of the swathe after operation.

DR. NOBLE: I tell my patients to wear one for a year, but a swathe can do little good unless a woman has a pendulous abdomen, except in so far that it reminds her that she has had an operation performed and must be careful. I have been asked as to the cumol catgut. In my experience it has been perfectly satisfactory.

DR. G. W. W. BREWSTER: It has seemed to me that in some cases in using the through-and-through suture trouble comes from tying the stitches too tightly, and therefore it is sometimes of advantage

to do the first dressing sooner than a week and cut one or two stitches if any appear too tight.

Dr. F. H. Davenport: I use the through-and-through method, except that in very fat women I put a suture in the aponeurosis of silk or catgut, feeling that the aponeurosis is the most important structure. My relatively few hernias have been where drainage was used or a second laparotomy was done. I cannot but feel that there is danger of infection if the wound becomes exposed to the air. Frequent changing of the dressing can avoid this, and accordingly it is my custom to change the dressing after forty-eight hours and every day after that.

Dr. Malcolm Storer: I have been struck by the tendency of the scar of the intracuticular suture to spread out after six or more months. Of late it has been my practice to sew the peritoneum, muscle and aponeurosis in layers, and then use interrupted silkworm sutures through the skin and fat, catching up a little of the aponeurosis in the median line to avoid a dead space. Since I have employed this method the scars, seen after a few months, seem to be much more linear and firm.

Dr. Noble: I am surprised that here in Boston the through-and-through suture should still find so many warm advocates. The researches of Winter ten years ago and Abel more recently showed that hernias are ten times as apt to occur with the through-and-through suture as with the tier suture. I used the through-and-through method myself until 1892, and I had certainly five per cent. hernias. Of course then I drained more than I do now, and so would expect more hernias. Tying sutures too tightly has more to do with suppuration than infection. I have not been troubled by the dead spaces spoken of, nor have I had any trouble with hemorrhage after tying with catgut.

Dr. F. H. Davenport showed a

FIBROID, TEN CENTIMETRES IN DIAMETER, REMOVED BY MYOMECTOMY.

Recent Literature.

The International Text-Book of Surgery. By American and British Authors. Edited by J. Collins Warren, M.D., LL.D., Professor of Surgery in Harvard Medical School; Surgeon to the Massachusetts General Hospital, and A. Pearce Gould, M.S., F.R.C.S., Surgeon to the Middlesex Hospital; Lecturer on Practical Surgery and Teacher of Operative Surgery to the Middlesex Hospital Medical School, etc. Vol. I, General and Operative Surgery. Pp. 947, with 458 illustrations in the text and nine full-page plates in colors. Philadelphia: W. B. Saunders. 1900.

This work is intended to furnish a reliable text-book of surgery, one "untrammelled by the many traditions of the past, and which presents with due discrimination the results of modern progress." Recognizing that the broad field of special surgery has made it practically impossible for any one writer, however brilliant, to be omniscient, the editors (who, as is well known both in this country and abroad, are men exceptionally well qualified to prepare such a work) in order to accomplish their purpose have obtained the assistance of others, notably experts in their special departments of surgery. These are men of wide experience and international reputation. They have contributed extensively.

The book is to be published in two volumes. Vol. I is now placed at the disposal of the profession and others who may be interested. It treats of General and Operative Surgery. Vol. II is to contain the chapters devoted to Special or Regional Surgery.

Vol. I, the one just published, is an exceedingly handsome, attractive book. Our space will not permit us to enumerate in detail the subjects included in its table of contents. The usual ones appear and also some unusual ones, such as Surgical Pathology of the Blood, Constitutional Reaction to Wounds and Infections, Surgery of Muscles, Tendons and Bursæ, of the Heart and Blood-Vessels, etc. Some subjects are treated with much more care and detail than is usually observed, for example, the chapter of 25 pages on Anesthetics and Surgical Anesthesia.

The articles as a rule present the essentials of the special subject treated in a clear, concise manner. They are systematically written. The subdivisions are readily distinguished from the general text by the lettering at the commencement of each paragraph, a method which greatly facilitates rapid reference. The book is extensively indexed. The illustrations are abundant, well chosen and enhance greatly the value of the work.

The chapters are often excellent résumés of the more detailed publications of their authors. The present status of some of the more recently investigated lesions is well described, for example, "traumatic" and "congenital" dislocation of the hip. The book is a thoroughly modern one. As is unavoidable, when so much has to be condensed into a limited space, some chapters are very concisely written; but the general ground has been well covered, the main facts have been presented, and the student can be sure that, when he has thoroughly studied the volume and has familiarized himself with its contents, his general knowledge of modern surgery will be up to date. The presswork of the book is highly satisfactory. The second volume will be awaited with interest.

Brain in Relation to Mind. By J. Sanderson Christison, M.D., author of "Crime and Criminals"; formerly of the New York City Asylum for the Insane, etc. Pp. 143, illustrated. Chicago. 1899.

The author has tried to present in this book what is known of the relationship of the brain to the mind, and give the facts indicating the present status of our knowledge. He has tried to state facts, rather than present arguments, and to establish those facts by the necessary references. Cerebral development functions, the significance of brain contour and size, and mind localization are among the subjects discussed. The book deals with a subject of interest to the physician, the lawyer, the theologian, and the psychologist.

A Case of Leprosy. — A young man, twenty-two years of age, who recently arrived in New York from Bridgetown, Barbadoes, was discovered by the examining surgeon of the Immigration Bureau to be suffering from leprosy, and was immediately ordered back to the steamship on which he had come as a steerage passenger, for deportation.

THE CONTROVERSY AS TO THE NUTRITIVE VALUE OF ALCOHOL.

THE results of some recent experiments conducted by Dr. Atwater, of Wesleyan University, upon the nutritive value of alcohol, have awakened anew a vigorous controversy upon one of the important questions of education, the teaching in regard to alcohol in the schools.

Dr. Atwater claims in his published statements that the results of his experiment prove that alcohol is a food, and that therefore the teaching of pulpit and schools that it is not a food is an error, and should be discontinued. The adherents of temperance and of the present method of teaching in regard to alcohol have replied in several letters, and finally by a pamphlet called "An Appeal to Truth," stating that Dr. Atwater's experiments do not prove that alcohol is a food either in the common sense of the term, as understood by people generally and used in books of hygiene, or in the particular sense in which the author uses it, as a food entitled to rank as sugar, starch and fat, and that, therefore, his experiments should have no effect upon the teaching.

The question in dispute in this case is not the actual value of alcohol as a food, but is solely whether or not the conclusions which Dr. Atwater draws from his results are justified by these results.

These conclusions, stated in Circular No. 357, November 6, 1899 (U. S. Department of Agriculture, Division of Publications), are:

(1) That the alcohol was almost completely oxidized in the system.

(2) In the oxidation all of the potential energy of the alcohol burned was transformed into heat or muscular energy.

(3) That the alcohol protected the material of the body from consumption just as effectively as corresponding amounts of sugar, starch or fat.

If we examine the experiments from which these conclusions are deduced, contained in Bulletin No. 69 (Office of Experimental Station, Department of Agriculture), in regard to each of the three conclusions separately, we find that conclusions Nos. 1 and 2 are perfectly tenable and justifiable on the basis of these experiments, but that No. 3 is not thus justifiable. The data given in the Bulletin show conclusively that alcohol is oxidized in the body and that the potential energy of this alcohol is transformed to heat or energy of some other kind. It fails, however, to show that the alcohol protects the body materials from consumption equally with sugar or starch or fat. In fact, this data shows an actual loss of nitrogen in the experiments in which alcohol was used, proving a consumption of body material under these conditions. We are thus forced to conclude from an examination of the facts that the authors of "An Appeal to Truth" are correct in their claim that Dr. Atwater's experiments do not justify his statement that alcohol is a food entitled to rank as sugar, starch or fat in its effect in protecting the body materials from consumption. In fact, the experiments as they stand prove the contrary.

Are they justified also in their claim that his experiments fail to justify him in his conclusion that alcohol is a food in the ordinary sense of the term, a conclusion implied in his statements in the report which refer to alcohol "with other food materials"? We think that they are so justified.

The two conclusions in regard to the metabolism of alcohol which Dr. Atwater's experiments did warrant, namely, that alcohol is oxidized in the body, and that the potential energy of the alcohol is there liberated, do not by any means prove that alcohol is a food in the ordinarily accepted sense of the term "food." To demonstrate this fact, it must be proven that the sum total of the effect of the ingested alcohol is useful rather than harmful in the maintenance of the animal economy. And this Dr. Atwater has not proven. And it has not yet, as far as we know, been demonstrated by any experiments. In fact, the weight of experimental evidence at the present time is decidedly against such an assumption. Thus the experiments made upon large bodies of men under conditions of sustained labor, as those conducted in the English, German and American armies, prove to us that the effects of the use of alcohol, in the amounts ordinarily spoken of as "moderate," make the soldier less rather than more fit for work, and decrease rather than increase the amount of energy which he can put forth under given conditions. That the use of alcohol in large amounts is harmful no one doubts.

It is possible that it may some day be proven that the effect of very small amounts of alcohol upon the economy is such as to entitle it to be considered as a food. But it has not yet been so proven. And until it is, the advocates of the temperance education are quite justified in any protest which they may make against the assumption that alcohol is a food.

As we have said, the whole truth in regard to the action of alcohol in the body or the question of its nutritive value is not known. If it is at some future

time proven that small amounts have such a value, then alcohol must be classed as a food.

It must be pointed out, however, that even such a result would not entitle it to be classed as a desirable or hygienic food, which is the sense in which people in general understand the meaning of the term "food." Against such inclusion there are many weighty arguments, as, for example, the fact that the tendency to the formation of the alcohol habit from taking these small amounts is so great that the danger of its use far exceeds any possible benefits which may be derived from it.

These remarks are not intended as a justification of *all* the teaching upon the subject of alcohol which has up to the present time been advocated or employed by the agents of temperance education in the schools. We wish merely to point out that, in regard to the teaching upon this particular question, as to whether or not alcohol is a food, their position has not yet been successfully controverted by scientific evidence. Whether the present teaching upon this point is the wisest under present conditions of knowledge is another question.

It is our personal opinion that the wisest course at present would be to base the prohibition of alcohol advocated in the teaching upon the fact that alcohol is an undesirable substance, the use of which in any capacity in health is quite unjustifiable under the laws of hygiene, rather than upon the statement that it is not a food or the unqualified statement that it is a poison. For while the latter statements in unqualified form have, at the present time, the preponderance of scientific evidence in their favor, still our knowledge in this regard is not complete. The former statement, however, is based upon facts and arguments so established that it may be regarded as true beyond the shadow of a doubt.

TWO VOLUMES OF "PROCEEDINGS."

The growth of medical knowledge, unfortunately, does not keep pace with the growth of medical literature. Journals are multiplying beyond all necessity and demand, and each special branch has also its special organ. In addition to this, medical societies are increasing in number, as representing certain sections of the country or special interests, and hence is born another species of medical literature, the proceedings or transactions. Of these we now have two bulky volumes before us, one the *Proceedings of the American Medico-Psychological Association* for 1899, and the other Volume 1 of the *Transactions of the Mississippi Valley Medical Association* for the same year. The first is, of course, a collection of special papers relating to the problems and interests of psychiatry. A notable contribution is the one by Dr. Peterson, of New York, on methods of study and improved facilities in our large cities. He speaks highly, and with reason, of the comprehensive laboratory inaugurated by Van Giesen for the study of mental disorders, and strongly advocates the establishment of what he calls "psychopathic hospitals" (the term is hopelessly bad) for the reception of the acutely insane. The volume should be of much interest to psychiatrists, and of some interest to all of us, but the papers, with few exceptions, lack the stamp of real originality and personal research.

The *Transactions of the Mississippi Valley Medical Association* is a very different sort of a book. It has a wide scope of subjects, under forty-seven titles, — papers of personal experience in great part. No doubt, for members of the Association, such a collection of uncritical papers has a certain interest and value; for the rest of the world, we confess to the conviction that it adds to the bulk but not to the worth of existing medical literature. It is usually a misfortune that an author writes a paper for such a volume, with the consciousness that it is first to be read at a meeting. The tendency to deviate from direct statement into the vagaries of fine writing is apparently quite irresistible, under such circumstances. It is hard for some of us to learn that in dealing with a subject of scientific character, an absolutely direct style of expression is alone admissible.

MEDICAL NOTES.

Pollution of Water Supplies. — A bill has been introduced in Congress relating to the pollution of water supplies. The bill provides for an appropriation of $3,000 to enable the Marine-Hospital Service, under the direction of the Secretary of the Treasury, to investigate the sources of contamination of rivers and other natural sources of water supply where the sanitary condition of the people of more than one State or Territory or the District of Columbia is affected, the first investigation under the provisions of the bill to be made of the Potomac River. At the instance of the Game and Fish Protective Association of the District of Columbia an amendment has been adopted by the committee providing for an appropriation of $2,000 to enable the Commissioner of Fish and Fisheries to investigate and report on the effects of pollution in interstate rivers upon the fish, fry, spawn, fish-food, plankton and riparian vegetation of such waters. It is of interest in this connection to note that Massachusetts alone, through its Board of Health, expends $30,000 yearly for the prevention of river and stream pollution. The foregoing bill savors somewhat of a union between the Marine-Hospital Service and the Game and Fish Protective Association, to be used by the former as an entering wedge to larger things.

Antivivisection Estimates of the Value of Serums. — While the Treasurer of the New England Antivivisection Society is informing a committee of the Massachusetts Legislature that Haffkine's antiplague inoculations have been proved to be worthless, the Indian Plague Commission is reporting to the Under-Secretary of State for India, that they "consider Mr. Haffkine to have performed a great life-saving

work in the face of almost insuperable difficulties." They express their sense, after very careful investigations, of the importance of the method which Mr. Haffkine has devised and of the results which have been achieved by it. As the same official of the Anti-vivisection Society informed the same legislative committee that the only value of antidiphtheritic serum resided in the carbolic acid by which it is preserved, and that, notwithstanding the proved worthlessness of the antitetanus serum, doctors go on just the same injecting it into the brains of their patients, thoughtful and serious people may afford to disregard his statements and his conclusions.

THIRTEENTH INTERNATIONAL MEDICAL CONGRESS. — A circular has been issued by the General Secretary of the Congress, giving information to members who propose to attend. Each member has the privilege of participating in the work of any of the sections. Reports of proceedings will be sent to each member, but only in that section to which he, personally, belongs. In addition to this, each member will receive later, without charge, a volume containing a general résumé of the work of the Congress; also a volume giving a complete account of the general assemblies. Other volumes may be purchased, if desired.

ANOTHER ANTIVIVISECTION BILL. — The indefatigable Dr. Gallinger has introduced in the United States Senate a new bill which reads as follows: "That no person shall perform upon the body of any human being in the District of Columbia any scientific experiment involving pain, distress or risk of life and health, whether by administration of poisonous drugs for the purpose of ascertaining their toxicity, by inoculating the germs of disease, by grafting cancerous tumors into healthy tissues, or by performance of any surgical operation for any other object than the amelioration of the patient."

UNIVERSITY MEDICAL MAGAZINE. — It has been announced that the Board of Trustees of the University of Pennsylvania has finally secured entire control of the *University Medical Magazine*, and that in the future it will be published under the auspices and with the support of the University. Heretofore the publication has been in the hands of a stock company, over which the University had no control. Dr. Charles H. Frazier has recently been appointed editor.

NEW ORLEANS POLYCLINIC. — A report has been circulated that the New Orleans Polyclinic has been suspended on account of small-pox in New Orleans. This is incorrect. The small-pox situation in New Orleans has at no time justified any apprehension on the part of students attending the Polyclinic or on the part of those who might wish to do so.

THE GERMAN CONGRESS OF INTERNAL MEDICINE. — The eighteenth German Congress of Internal Medicine will be held at Wiesbaden, April 18th to 21st. Professor von Jaksch, of Prague, is the president. A discussion on the "Treatment of Pneumonia," is announced, and also one on "Endocarditis and its Relations to other Diseases."

TUBERCULOSIS IN FRANCE. — A bill providing for the erection of a national institution to combat tuberculosis has been introduced into the French Chamber. It is said that about 150,000 deaths annually in France are due to tuberculosis.

RETURN OF SIR WILLIAM MACCORMAC. — Sir William MacCormac, President of the Royal College of Surgeons, who has been acting as volunteer surgeon with the British Army in South Africa, has sailed for England.

APPOINTMENT OF DR. LEWELLYS F. BARKER. — Dr. Lewellys F. Barker, of the Johns Hopkins Medical School, has been appointed professor of anatomy in the University of Chicago and Rush Medical College.

HOSPITAL BEQUESTS. — Under the will of the late Siegfried R. Zunz, of Wimbledon, it is reported that the London, England, hospitals will benefit to the extent of between $400,000 and $450,000.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, March 7, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 69, scarlatina 42, measles 104, typhoid fever 15.

MORTALITY STATISTICS IN BOSTON. — The total number of deaths reported to the Board of Health for the week ending March 3d was 273, against 187 the corresponding week last year, showing an increase of 86 deaths, and making the death-rate for the week 25.7. Of this number 136 were males, and 137 females.

CHRISTIAN SCIENCE AND DEATH CERTIFICATES. — A child has recently died in Somerville, Mass., who had been treated by a Christian Scientist; he gave as the cause of death, pneumonia. The clerk of the Board of Health declined to issue the burial permit without the testimony of an accredited physician, as required by law. After considerable controversy, in which the clerk was upheld in the position he had taken, a physician was allowed to view the body, and the burial was permitted.

A CASE OF SMALL-POX AT YALE. — It is reported that a student in the Freshman Class of the Sheffield Scientific School is ill with small-pox. Very few of his classmates have been exposed to contagion, and with the precautions that have been taken, it is not expected that the disease will spread.

A CENTENARIAN. — Mrs. Abigail Kimball Garvin died in Westford, Mass., March 2d, at the age of one hundred and four years.

NEW YORK.

AN IMPORTANT DECISION. — A will case that has attracted much public interest has just been decided in

the courts. The will in question was that of Miss Annie Taylor Morgan, who is believed to have lost her life at the Windsor Hotel fire on March 17, 1899, and it has now been admitted to probate by Surrogate Thomas. The main ground of contest was that there was no proof of the death of the testatrix. The Surrogate decides that the evidence of her death, though circumstantial, was entirely sufficient. From the time of the fire until now no friend of the testatrix has seen her or heard from her. Only one witness, the Surrogate states, was willing to express an opinion that the testatrix was insane. The evidence on that point, however, amounted to little. By the provisions of the will Miss Morgan's estate is left to a god-child, and the contest was brought by her sister, from whom she had long been estranged.

Resignation of Dr. Charles McBurney. — Dr. Charles McBurney has resigned his position as attending surgeon to the Roosevelt Hospital, and the announcement is received with great regret and considerable surprise by the profession. Dr. McBurney has been identified with Roosevelt during its entire existence, and it was on account of the high esteem felt for him that the Sims Operating Pavilion, one of the most completely equipped establishments of the kind in the world, and which was erected and fitted up under his personal supervision, was added to the hospital.

Miscellany.

ANOPHELES AND MALARIA.

A valuable paper by Professor Celli, the Director of the Institute of Hygiene in Rome, has appeared in a recent issue of the *British Medical Journal*. The following comments are made editorially:

"The older observers had noted, what is indeed a part of the folk-lore of malarial districts of Europe, that malaria was most likely to be contracted about sunset and at night. *Anopheles* lies hid by day and issues forth in quest of human blood at sunset, and pursues its search through the night. Again, the old observers noted that the malarial 'miasm' was often very limited, and did not extend to any great elevation, so that residence on the top of a rock or in the highest story of a lofty house was some protection. It is known that the mosquito does not fly far from its birthplace, nor mount high in the air. Again, the older observers knew that the malarial 'miasm' was not carried by high winds, and it is notorious that the mosquito does not fly on stormy nights.

"Professor Celli thus traces the cycle, for the maintenance of which, in Italy at least, man is essential. Beginning with the great multiplication of mosquitoes at the end of June or the early part of July, it is found that some of these are infected by the malarial parasite. They convey the infection to man, thus bringing about the great increase in the number of attacks of malaria observed in July and August, but sometimes continuing into the fourth quarter of the year. During the first and second quarters of the following year the malarious cases met with are generally recurrence of the infections contracted in the third or fourth quarters of the preceding year, and it is by these recurrent cases occuring even as late as June, when the mosquito once more becomes active, that the infection is again transmitted to the insect, and a new epidemic started.

"Professor Celli observes incidentally that in Italy children are more affected by malaria than adults, and Professor Koch lays great stress upon this point, making it indeed the test of the extent to which malarial prevails in a population, since he finds evidence that adults in a malarial district having survived the infection in early youth have acquired a more or less complete immunity. This observation Koch believes may be of great importance in prophylaxis.

"Both Celli and Koch lay great stress on the part which the cultivation of rice plays in favoring the multiplication of mosquitoes. 'The more rice fields,' Koch reports, 'there are in the neighborhood of a place, and the nearer they are, the greater the abundance of mosquitoes;' and Celli observes that it is well known that 'the formation of rice fields causes the reappearance of malaria where it had become extinct, and where it already exists they are a very active focus of production.' Rice is best cultivated on low lands subject to occasional inundation, but where inundation cannot be depended upon very copious artificial irrigation is resorted to."

Correspondence.

[Special Correspondence.]

LETTER FROM PARIS.

Preparations for the Exhibition. — The International Medical Congress. — French Spleen as Manifested towards Americans and English. — To Attend or Not to Attend the Exhibition and the Congress?

Paris, February 22, 1900.

Mr. Editor: — We whose lot it is to live in Paris have been made very painfully aware during the past year that the great Exhibition of 1900 is fast drawing near; the town has been simply torn up by the roots in its preparations for the event, and life has thereby been rendered loathsome. Immense groups of buildings going up, others being pulled down, three sections of underground railways being hurried through at once, long quays being constructed on the river banks, rails being laid in many streets for electric tram-lines, two fine railroad termini being erected, the direction of some of the main sewers being altered, the Seine being bridged in several places, etc., have thrown the city into such a state of chaos as the oldest inhabitant has never witnessed, unless during the Commune, if even then. During this Exhibition, as your readers are undoubtedly aware, is to be held the Triennial International Medical Congress, and it is of this Congress that I wish to say a few words today.

As regards the general utility of these great medical conclaves I think there is practically but one opinion: nothing of real importance has ever been brought forth at any of them. This is so true that the tendency now appears to be for leading medical men to hold aloof from them, or, at any rate, only to appear *pro forma*, reserving their interesting communications for the societies and periodicals with which they may happen to be personally affiliated. This leaves the arena to the young and ambitious, who have had things pretty much their own way at the last two or three congresses. Some of the communications at Berlin and Moscow on the part of unknown members of the

profession were so utterly valueless, and such unabashed attempts at self-advertisement, as to call forth universal remark at the time, followed later on by a variety of proposals for modifying the method of holding the sittings so as to put a stop to this abuse.

Furthermore, the number of medical men with or without encumbrances who attend these gatherings appears to be steadily on the increase, so that at the more recent ones the crowd has become practically unmanageable. Whence the occurrence of a great deal of sore feeling and wounded susceptibilities, the local committees being incapable of singling out the grain from the chaff, and powerless to pay proper attention to the lights of the profession, even when discovered, owing to their necessarily restricted numbers. If this has been the case in what may be called uneventful years, and in such relatively unfrequented centres as Berlin, Moscow and Rome, what are we to expect in an exhibition year, and in such a universal rendezvous as Paris? The thought of the herd of physicians that will congregate here next summer makes one positively shudder.

If, now, to this we add that the unfortunate committee has appointed as the date of the Congress August 2d to 9th, a time of year when the atmosphere of Paris, without reaching the lofty summits of heat with which many Americans are familiar, is absolutely dead and filled with stenches, and also that the majority of the attendance will be composed of the great unwashed populations of the Continent, to whom an open window is the height of abomination, and who will crowd the stifling assembly rooms and then sit and sweat and sweat and sweat again, the prospect for the fresh-air, English speaking delegates to this Congress may be realized.

I see on the north bank of the Seine, in full exposure to the sun, a light shell of a building of great size, marked: *Palais des Congrès*. I have not heard whether the intention is to hold the Medical Congress in this building, but, if such is the plan, all I can say is that the members attending will have my profoundest commiseration and that there is, at any rate, one practitioner in this city who will be conspicuous by his absence. Under an August sun that edifice will be a furnace.

Let us consider for a moment what can be the expectations of the average American physician in attending this Congress — I mean those who may intend to come unofficially and not as delegates. I think that a certain number will look on the Congress as a sight to be seen with the other sights of Paris during their summer trip abroad. Others, and this appears to me to be the only real purpose that can be attained at these congresses, will come to it to extend their circle of acquaintances, to meet many confrères with whom they are in correspondence and of whom they hear from mutual patients, or to see the celebrated men whose publications they read and in whose work they may be specially interested. Others, still, will come to look into medical Paris of to-day, to visit the hospitals, clinics, laboratories and museums, and to see what ideas they can discover worth noting and transplanting to America. Will the pains of the latter be rewarded; will the results they can expect to obtain be worth the trouble, expense and loss of time the journey will entail?

Unfortunately, I am obliged to give a decidedly negative answer to these questions. No; there is not enough for American physicians to learn here to warrant the undertaking; any one having the time and means to take the trip, if for medical purposes only, can accomplish far more by visiting Vienna or Berlin than by coming to Paris. It is positively melancholy that a great medical centre like Paris, which, no further back than thirty or forty years ago, led the world, should now occupy the position it does. The foreign *clientèle* of the French medical schools is now composed almost exclusively of the Southern and far Eastern races: South America, the Spanish Peninsula, Greece, Egypt, Turkey, Roumania, Southern Russia and Siberia. The more progressive and highly cultured countries are conspicuous by their almost total absence, and no further proof then is needed to show the superiority of the other great medical centres over Paris.

I do not propose to go into the details of medical teaching and practice in Paris in this letter; they would take up too much space, and I hope to treat this point in full on some future occasion. But in general terms I can say that all is anarchy *in rebus medicinæ* in Paris. There are brilliant exceptions, naturally. Many of the professors are most gifted men; a few of the clinics are practically up to date (though in such cases this is generally due to altogether private efforts on the part of the *chef*); one at least of the museums is unique, and on several hospitals a great deal of money has been spent lately, with results not proportionate to the expenditure. But on the whole, the American will meet with more surprises and disappointments than with anything else.

There are, as I have said, many excellent men as professors; the clinical material has simply no limits; the facilities are all that one can ask, and there are plenty of funds. Yet the net result produced is so poor as to be positively astounding. The cause of this miscarriage of effort appears to me to be the fact that medical affairs in France are a monopoly held by the Government, and are run on the lines of a great "administration," like any other "administration," such as the post-office, for instance. They are entirely managed by officials, who in this instance, as in all others in this country, throw a withering blight on whatever they are brought in contact with. Competition is absolutely excluded, there being no degrees conferred except by the Government Faculties, of which there are only half a dozen for the whole of France. Finally, one is forced to admit the existence in the French either of inability to grasp the value of certain things they see in hospitals abroad, or else of deliberate unwillingness to make any innovation that has not its point of departure in their own country. For instance, how is it possible otherwise to comprehend a national medical system in a great country at the end of the nineteenth century in which the hospital trained nurse, as evolved in England and America, is otally unknown?

In conclusion, I wish to allude briefly to a somewhat delicate side of the question of American attendance at the Paris Congress this summer. Politics are not at home in the columns of a medical journal — that I know; still, there are some things that one *has* to say, and the one I now have on my mind is that I shall be very sorry to see my American confrères contribute to the success of this Congress.

It is evidently difficult to make people who live at a distance in America appreciate what the feeling of the French is toward the English-speaking races, or what occurred here during our war with Spain, and is now occurring again while the English are at war in South Africa. There is something about the English-speaking peoples that creates a profound aversion in the French mind. This they admit themselves with perfect candor. Under ordinary circumstances, when the political atmosphere is relatively calm, this aversion is kept more or less out of sight, and is covered over with a superficial veneer of ceremonial politeness. The English or American who during such periods visits France, and is only thrown in contact with the French in a casual way, is apt to depart *charmed* with French politeness and affability, and I for one do not blame him. The French are simply *passed masters* in this art, and although I have lived here a great many years, am beginning to understand my Frenchman fairly well, and am quite on my guard, it is even now *almost impossible* for me to avoid being taken in by the Frenchman's *apparent* cordiality and courtesy.

But let some great political cataclysm occur — the war with Spain, Dreyfus case, or the present war in South Africa — you at once see the Frenchman *as he really is*. The superficial shell of good manners behind which he has been concealed falls from him, and you behold a man whose hatred of everything English (in which he includes everybody who speaks the English tongue) is rendered doubly bitter by being long contained, and generally very ignorant of all that concerns the object of his hatred.

Such an outburst of gratuitous insults, venomous lies and

outrageous attacks of all sorts against Americans as filled the French press during our war two years ago must be almost unparalleled; and now that the process is being repeated against the English in connection with the South African War, I am almost led to believe what I have several times heard said, that the animosity of the French toward the English is more intense than their feeling against the Germans.

Let me merely give one or two instances of the violence of this feeling, and the undisguised way in which it has been manifested of late, so that no one will think I am exaggerating.

During our war I, personally, saw a Frenchman come up behind an English lady seated in a cab and try to knock her sailor hat off, the endeavor only failing by the hat being held by long pins run through her hair; this attempt caused great satisfaction to those who saw it, and to a policeman a few yards away, who made no step to interfere.

During the Spanish War, Dreyfus case and present African War, it has hardly been safe for an English-appearing woman to go on the streets of Paris unaccompanied; she is liable at any moment to have the epithet, "*sale Anglaise*," hurled in her face, as has happened any number of times to ladies whom I know — once recently on the Champs Elysées, in the afternoon, by a soldier in uniform.

The last few weeks have seen the appearance of a new form of ventilating the French spleen. Placards have been posted in different parts of Paris, reading: "*Mort aux Anglais.*" I saw a paper being sold along the boulevards the other day, that had those words printed in an immense heading running across the page, so that every one could read them at a distance. Finally, on entering a suburban train recently I found the carriage sides plastered with little printed labels bearing the same amiable inscription.

These are only samples of the electricity there is in the air here, and of the true feelings of the French toward us. It is quite possible that the anti-English campaign will be lulled during the Exhibition, and that the more usual appearance of affability will come to the front again, as the French are not *quite* easy in their minds about this Exhibition. They know that their best foreign customers are the English and Americans, and certain warning notes have already appeared in their papers about not carrying their insulting tirades and caricatures too far.

But whatever they do, their *true* feeling toward us is as I have described it. Americans should know what it is, and should bear in mind their scurrilous behavior to us during our war, and what they would have done in the way of intervention if they had not felt Great Britain in their way.

Let the members who do attend this Congress take the greeting of the French at its *real* value, and not at all for what it *appears* to be worth. SPECTATOR.

STREET PAVEMENTS.

BOSTON, March 3, 1900.

MR. EDITOR: — Permit me a few words in reply to the editorial comments on my communication in the last number of the JOURNAL. I did not mention the names of Dr. Durgin, Professor Allen and Mr. McClintock, because I was not sure of them and therefore spoke of these gentlemen collectively as experts, thinking that I was thus showing due regard to their opinions. As to Mr. McClintock, he gave an account of macadam roads, but said nothing, I believe, about asphalt *pro* or *con*. The letters you publish I had the pleasure of hearing read at a meeting before the Park Commission a few years ago. They present strong evidence, but it is only just to say that the Brick Paving Company also produces many testimonials and statements as to the superiority of brick. A book on this subject with the title of "Brick Roadways" was distributed some years since, and doubtless many of your readers possess it. A gentleman who lives on Arlington St., opposite the portion laid with brick, tells me that this makes an admirable pavement, and there are abundant proofs that it can be made to wear well.

Horses require no special shoe to travel over it, and water can be used freely on it. Asphalt is certainly a boon to the street superintendents, who find a company ready to put down a roadway and keep it in repair, but it is not so great a boon to the public, in a changeable climate like ours. Its disadvantages are not imaginary, but real and easy to verify. London may be called as a witness. London has tried asphalt and returned to wood pavements, preferring comfort to durability. Regarding the use of wood, I find in a recent magazine this statement.[1] "Improved wood pavements are a luxury. They have many points of superiority over asphalt. They are so considered in London, where their use is continued, although they require renewal oftener than asphalt, and much more often than granite. They will undoubtedly be used more frequently in this country, when the people are willing to pay the additional cost for the quiet and freedom from dust, and from the somewhat disagreeable glare of asphalt." As for local testimony against asphalt, there was a letter published in the *Boston Transcript* of February 24th, by John F. Ryan, M.D., which is worthy of attention.

Yours truly, S.

AN EXCURSION TO THE PARIS EXHIBITION.

HARTFORD, CONN., March 5, 1900.

MR. EDITOR: — An excursion to the Paris Exposition and the International Medical Congress, to be confined exclusively to physicians and their families, has been organized in the West. Two steamers have been chartered, one the *City of Rome*, and the other the *Nebraska*. They will sail from New York on June 30th, and return in forty-five or fifty-two days, according to the wishes of the excursionists. A New England Committee has been appointed to solicit physicians in this part of the country who would like to make this excursion. The expenses, including hotels, carriage drives, etc., also including a tour through Scotland, Ireland, England, and Belgium, will be from $260 to $285. The return can be made any time during the year. A large number of physicians are arranging to go on this excursion, which promises to be one of the most enjoyable of the year. The New England Committee are H. O. Marcy, M.D., Boston, Mass.; E. R. Campbell, M.D., Bellows Falls, Vt., and T. D. Crothers, M.D., Hartford, Conn. Each one of these gentlemen would be pleased to give all information, and to send circulars of the itinerary of this trip to any who may wish to join it. Over 200 have already been booked, and the prospect is that both ships will be crowded. It is necessary that any person wishing to join this excursion should communicate at once with the Committee.

Very truly yours,
T. D. CROTHERS, M.D.

THE DISCOVERY OF THE BACILLUS OF INFLUENZA.

PORTLAND, MAINE, March 5, 1900.

MR. EDITOR: — In your issue of March 1st is a review of Dr. W. H. Park's "Bacteriology," the review being chiefly a list of "errors or special defects." In this list appears the following finality: "On page 30 Canon is erroneously credited with a part in the discovery of the bacillus of influenza."

It may be now within the knowledge of your reviewer that Canon is a pretender; but in Berlin, in 1892, Canon was the flushed and happy recipient of congratulations for a discovery simultaneous with that of Pfeiffer.

Very truly yours,
ADDISON S. THAYER, M.D.

Deaths reported 2,817; under five years of age 980; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping-cough, erysipelas, fevers and consumption) 584, acute lung diseases 713, consumption 288, diphtheria and croup 103, measles 74, diarrheal diseases 37, typhoid fever 34, scarlet fever 27, whooping-cough 25, erysipelas 16, cerebrospinal meningitis 10.

From diarrheal diseases New York 20, Pittsburg 5, Providence 4, Charleston and Fall River 3 each, Baltimore 2. From scarlet fever New York 17, Boston 5, Baltimore, Providence, Somerville, Lawrence and Gloucester 1 each. From whooping-cough New York 16, Boston 4, Pittsburg 2, Providence, Nashville and Lawrence 1 each. From erysipelas New York 12, Boston, Cambridge, New Bedford and Somerville 1 each. From cerebrospinal meningitis New York 5, Boston and Baltimore 2 each, Somerville 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending February 10th, the death-rate was 22.8. Deaths reported 5,082: acute diseases of the respiratory organs (London) 425, whooping-cough 138, diphtheria 115, measles 82, diarrhea 39, scarlet fever 37, fever 34, small-pox (Hull 3, Leeds 1) 4.

The death-rates ranged from 12.6 in Cardiff to 35.1 in Preston: Birmingham 22.0, Bradford 21.8, Bristol 19.4, Gateshead 17.6, Hull 25.8, Leeds 29.4, Leicester 18.3, Liverpool 31.8, London 20.4, Manchester 28.0, Newcastle-on-Tyne 25.4, Nottingham 16.5, Sheffield 26.1, Swansea 15.8, West Ham 14.4.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,296, for the week ending February 17th, the death-rate was 25.8. Deaths reported 5,750; acute diseases of the respiratory organs (London) 527, whooping-cough 138, measles 132, diphtheria 102, fever 33, scarlet fever 31, diarrhea 31, small-pox (Hull) 2.

The death-rates ranged from 14.3 in Brighton to 34.8 in Preston: Birmingham 32.4, Bradford 18.4, Cardiff 15.8, Gateshead 30.5, Hull 24.7, Leeds 28.4, Liverpool 25.7, London 22.9, Manchester 37.2, Newcastle-on-Tyne 23.4, Nottingham 22.6, Portsmouth 25.7, Sheffield 26.5, Sunderland 26.5, West Ham 19.1.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 2, 1900.

F. W. OLCOTT, passed assistant surgeon, detached from the Naval Recruiting Rendezvous, Detroit, Mich., and ordered home and to wait orders.

J. A. MURPHY, assistant surgeon, ordered to the Pensacola Navy Yard.

W. F. ARNOLD, passed assistant surgeon, detached from the Pensacola Navy Yard and ordered to the Naval Hospital, Norfolk, Va., for treatment.

D. H. MORGAN, assistant surgeon, ordered home from the Asiatic Station and to wait orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING MARCH 1, 1900.

BROOKS, S. D., surgeon. To proceed to Bar Harbor, Me., as inspector. March 1, 1900.

PERRY, T. B., passed assistant surgeon. To proceed to Buckhannon, W. Va., for special temporary duty. February 26, 1900.

WOODWARD, R. M., passed assistant surgeon. Granted leave of absence for thirteen days from April 16th. February 26, 1900.

COBB, J. O., passed assistant surgeon. To proceed to Folsom and Catskill, N. M., for special temporary duty. February 27, 1900.

YOUNG, G. B., passed assistant surgeon. Granted leave of absence for one day. February 26, 1900.

TABB, S. R., assistant surgeon. To proceed to Fernandina, Fla., as inspector. February 24, 1900.

VON ECKDORF, R. H., assistant surgeon. To proceed to Atlanta, and report to the Governor of Georgia for temporary duty. February 24, 1900.

NEWBERRY, WALTER, hospital steward. Relieved from duty at the Tortugas Quarantine Station and directed to proceed to Mobile, Ala., and report to the medical officer in command for duty and assignment to quarters. March 1, 1900.

BECK, J. E., hospital steward. Upon being relieved from duty at Mobile, Ala., to proceed to San Francisco, Cal., and report to medical officer in command, for duty and assignment to quarters. March 1, 1900.

HOLT, E. M., hospital steward. To proceed to Boston, Mass., and report to the medical officer in command, for duty and assignment to quarters. February 28, 1900.

APPOINTMENT.

EDWIN M. HOLT, of Pennsylvania, appointed as junior hospital steward. February 24, 1900.

THE SAMUEL D. GROSS PRIZE.

ONE THOUSAND DOLLARS.

No essay which the Trustees deemed worthy of the prize having been received on January 1, 1900, they hereby announce that the prize will be awarded on October 1, 1901.

The conditions annexed by the testator are that the prize "shall be awarded every five years to the writer of the best original essay, not exceeding one hundred and fifty printed pages, octavo, in length, illustrative of some subject in surgical pathology or surgical practice, founded upon original investigations, the candidates for the prize to be American citizens."

It is expressly stipulated that the competitor who receives the prize, shall publish his essay in book form, and that he shall deposit one copy of the work in the Samuel D Gross Library of the Philadelphia Academy of Surgery, and that on the title page it shall be stated that to the essay was awarded the Samuel D. Gross Prize of the Philadelphia Academy of Surgery.

The essays, which must be written by a single author in the English language, should be sent to the "Trustees of the Samuel D. Gross Prize of the Philadelphia Academy of Surgery, care of the College of Physicians, 219 S. 13th St., Philadelphia," on or before October 1, 1901.

Each essay must be distinguished by a motto, and accompanied by a sealed envelope bearing the same motto and containing the name and address of the writer. No envelope will be opened except that which accompanies the successful essay.

The Committee will return the unsuccessful essays if reclaimed by their respective writers or their agents, within one year.

The Committee reserves the right to make no award if the essays submitted are not considered worthy of the prize.

W. W. KEEN, M.D.,
J. EWING MEARS, M.D.,
J. CHALMERS DACOSTA, M.D., } *Trustees.*

RECENT DEATH.

WILLIAM EDWARD WAMSLEY, M.D., of Brooklyn, N. Y., died on February 23th, at the age of forty-five years. He was graduated from the Medical Department of the University of the City of New York in 1877.

Original Articles.

INJURIES ABOUT THE SHOULDER AT BIRTH.[1]

BY J. S. STONE, M.D., BOSTON.

I HAVE been much interested in the injuries and deformities about the shoulder which are seen not infrequently in the clinics at the Children's and Infants' Hospitals. Most of these cases come under the general head of obstetrical injuries, and in most of them I have become convinced, partly from observation and partly from the rather scanty and very contradictory literature on the subject, that injury to the brachial plexus is by far the most important factor, while direct injury to bone and joint is of only secondary importance.

It has long been recognized that obstetrical paralysis is of Erb's type, that the deltoid is the muscle most seriously affected, and that the other muscles paralyzed are the supra- and infra-spinatus, teres minor, biceps, and brachialis anticus, together with the supinators. In some of the severer cases paralysis of some of the extensors of the wrist, or more especially of the fingers, also occurs.

All of the paralyzed muscles are supplied by the circumflex, suprascapular, musculocutaneous, and musculospiral nerves, including with the last its branch, the posterior interosseous. Of these nerves the circumflex, suprascapular and musculocutaneous arise entirely from the fifth and sixth cervical roots. In obstetrical paralysis these nerves are most seriously affected and every muscle supplied by them is usually paralyzed, excepting only the coracobrachialis, which is also supplied in infancy by a separate branch derived from the seventh cervical root.

The only other nerves which arise regularly from the fifth and sixth cervical roots are those to the scaleni, to the rhomboids, and to the subclavius, the posterior thoracic, a part of the external anterior thoracic, a very small part of the median, and the upper and lower subscapular, together with a small part of the musculospiral. Of these nerves the fibres which go to supply the scaleni, the rhomboids and the subclavius, and the fibres going to the posterior thoracic, leave the roots of the plexus almost immediately after their exit from the spinal canal and before the roots have joined to form the cords of the plexus. Furthermore, all of these nerves take a decidedly different course from the other nerves of the plexus. They do not go outward toward the shoulder. The pectoral and the subscapular muscles are supplied only in part by nerve fibres arising from the two upper roots.

As to the causation of the paralysis, I will mention, first, a theory which has been held somewhat in Germany, and which has been put forward in this country by Burr.[2] It is, in brief, that the lesion is a hemorrhage into the anterior horns of the cord, due to the congestion arising during birth. Burr argues in favor of this theory that sensation is unimpaired. His opponents reply that in infants this is an extremely fallacious sign, that complete recovery from an anterior poliomyelitis is rarely, if ever, seen, and that it is extraordinary that such a lesion should always occur at one particular spot. Furthermore, as Carter [3] points out, injury to the fifth and sixth cervical roots at or before their exit from the spinal canal may be excluded by the fact that the serratus magnus and the rhomboids, though supplied by nerves leaving these roots very soon after their exit from the canal, are never paralyzed. In other words, the lesion must be at a point below the origin of the fibres going to the posterior thoracic, to the rhomboids, and scaleni.

The other theories of the causation have been many. The theory of direct pressure on the plexus in the side of the neck, or axilla, by the blade of the forceps, the finger, or the hook, has been thoroughly discredited by the work of Carter, and more lately by Fieux,[4] among others. As Fieux puts it, whether the delivery be spontaneous, or whether extraction of the shoulders is necessary, whether coming on after the use of forceps or after a breech delivery, Erb's point is always pressed upon, and in one case by the posterior edge of the clavicle, in another by the fingers, in another by the edge of the forceps blade. Explanations of this sort obviously presuppose too much.

This brings up a point in regard to the etiology, on which there has been considerable discussion, the theory that the paralysis is due to a pinching of the plexus at Erb's point between the posterior edge of the clavicle and the first rib in cases in which the shoulder is carried far back. Some hold that the pinching of the plexus occurs between the clavicle and the transverse processes. These views are held by Oppenheim, Gault, Roulland, Budin, and of late have been advanced in Boston by Walton,[5] after anatomical study of a fetus at term, and more lately still by Schoemaker.[6] This pressure of the clavicle against the first rib, or the transverse processes, is an anatomical possibility. It means, however, that the shoulder must be carried considerably downward and very far backward to a degree which is at least not likely to occur during childbirth, although the theory that the pinching results from the rotation of the head, with the anterior shoulder hung up on the pubes, is attractive.

In the dissections on six babies which I have made the anterior curve of the clavicle gave ample space for the plexus not to be crowded. My conclusions agree absolutely with what I have since learned Fieux had done, but with which Schoemaker does not entirely agree; work bearing out in every way the theory ably set forth by Carter, that the paralysis is due to nerve stretching, and, in extreme cases, to nerve tearing.

The plexus arises from the fifth, sixth, seventh and eighth cervical, and first dorsal, nerves. If the shoulder is lowered it is plain that the upper cords must be stretched more than the lower, because the lower have normally a more nearly horizontal course. This is entirely confirmed on the cadaver. The upper two roots become as tight as bowstrings when the shoulder is lowered, while the lower three remain perfectly lax until the upper cords are severely stretched, or even completely ruptured. A pull down on the shoulder of about fifteen pounds is sufficient to break the upper roots when the plexus alone holds the shoulder up. A pull of about forty-five pounds, or three times as much, does the same thing when every-

thing is intact, except for a small incision through which to watch the plexus.

Fieux showed experimentally the amount of the separation of the cut roots of the brachial plexus when the shoulder was held down and the head carried to the opposite side with as much force as occurs in an ordinary delivery. He found that the upper two cords separated from 26 to 28 millimetres, the third only 12 and the lower two only eight. In other words, the upper two separated more than three times as much as the lower, and more than twice as much as the middle. The separation varies with the amount that the head is inclined to the opposite shoulder. It likewise varies with the amount that the shoulder is depressed.

The point at which rupture occurs, experimentally, is from about a quarter to half an inch from the emergence from the spinal canal, at or near the junction of the fifth and sixth cervical roots. The fibres of the suprascapular nerve may be ruptured here or at a point slightly lower. They are always ruptured among the first. This point is a little lower than that mentioned by Fieux, who states that rupture occurred five or six millimetres from the emergence of the nerves. The distance seems to be determined by the strength of the fibrous sheath which surrounds the nerve bundles. Very near the canal the prolongations outward from the dura prevent injury to the nerves. Farther out it is determined by a certain weakest point.

One very important point mentioned by Walton, which is admirably shown experimentally, is the fact that the suprascapular nerve must be severely stretched or ruptured, because it has a comparatively short course and what may be termed a very definite distal attachment where it passes through the suprascapular notch. Similarly, though to a less marked degree, the circumflex has a short course and a definite distal attachment where it winds about the humerus. In other words, these two nerves have but a short distance in which they can accommodate themselves to stretching.

Fieux produced by traction on the necks of rabbits, separating the head from the shoulder, a similar partial paralysis of the foreleg, but did not report the results of post-mortem examinations.

Cases reported by Phillips, Beevor, and Walton show similarly that a violent separation of the head from the shoulder may, in adults, cause a paralysis of Erb's type.

A degree of asphyxia leading to a loss of all muscular tone would obviously increase the danger of injury to the nerves.

In regard to the theory that fracture or dislocation of the bones may cause obstetrical paralysis, it should be remembered that paralysis from this cause in adults is not usually of Erb's type. Furthermore, certain anatomical facts in regard to the bony development at birth must be considered. The clavicle is osseous, except at the two ends, ossification beginning here earlier than in any other bone. The sternal and acromial ends are cartilaginous. The scapula at birth is cartilaginous along its whole inner border, at the angle, and in the acromion and coracoid processes. The main part of the body, the spine and the glenoid fossa are ossified.

The humerus at birth is ossified throughout the shaft; the head is cartilaginous. Thus the outer end of the clavicle, the coracoid and acromion processes are all cartilaginous and are all firmly united by strong ligaments. These parts making up the prominence of the shoulder are so freely movable and so strongly held by ligaments that injury to them is exceedingly unlikely to occur during birth. Injury to other parts is very much more likely to occur. Experimentally the cartilaginous head of the humerus is separated with great ease. The glenoid cavity may be broken off entirely by the exercise of considerably more force. The clavicle may be broken in its bony portion. The bony shaft of the humerus may be easily broken. Judging from what is seen experimentally, separation of the cartilaginous head of the humerus must be of extremely common occurrence during birth, and must often pass entirely unrecognized and indeed give rise to no symptoms, except the subjective one of pain, with perhaps a very soft crepitus which it would be impossible to detect with certainty during life. A fracture of a portion of the glenoid it is impossible to produce experimentally. The whole glenoid may be broken off. This would be an injury detected also with difficulty. Fracture of the clavicle and of the shaft of the humerus is in each case apt to occur about the middle of the bone and is detected with ease.

Experimentally, these fractures occur comparatively so easily that it is impossible by the use of any reasonable amount of force to dislocate the head of the humerus and practically absolutely impossible to dislocate the head of the humerus, if the word dislocation is used in the sense of forcing the head out of the glenoid through a rent in the capsular ligament. It is possible, with considerable force, to stretch and tear some fibres, particularly about the lower posterior part of the capsule.

It is perfectly conceivable that injury to the brachial plexus, through fracture of the clavicle, might cause paralysis of Erb's type, but it is likewise inconceivable that a fracture of the clavicle should very often pass undetected where there is an obstetrical paralysis. It is not possible for injury to any other bone than the clavicle to cause a paralysis of Erb's type.

It is, nevertheless, true that a considerable number of cases are recorded in which there is a backward displacement of the humerus, usually with paralysis of Erb's type, rarely without. My feeling in regard to these cases is that the dislocation, which is usually in the reports considered congenital, is in reality due to the paralysis; that is, that it is due to a slow yielding of the posterior part of the capsular ligament under the pull of the internal rotators. This form of dislocation was described by Dechenne in 1866. One case of backward dislocation has developed within my own observation during the second year of life. The child had a typical obstetrical paralysis, occurring after a version. When first seen the head of the humerus rested in the glenoid and could be slipped back onto its posterior border. When seen, a scant year later, the head rested outside of the glenoid and could be slipped forward onto its posterior border. This child has turned out to be microcephalic.

Another case had typical obstetric paralysis noticed immediately after birth, and examined by the family physician, Dr. Cahill, of Cambridge, who is positive there was no dislocation at first. I saw the child first at six months of age, when it was seen again by Dr. Cahill. The dislocation was then most striking.

Dislocation of this sort secondary to paralysis, whether or not accompanied by more or less tearing and stretching of the capsule at the time of the injury, is made much easier by the relatively small size, at birth, of the glenoid cavity as compared with the head of the humerus. Of course the disproportion is obvious in adults, but in infants at term the joint surface of the glenoid is in breadth only a quarter to a third of the diameter of the joint surface of the head of the humerus, while in adults it is one-half as large. In other words, the glenoid cavity is relatively from half as large again to twice as large in the adult as in the baby.

In obstetric paralysis the position of the arm is characteristic. It hangs at the side, rotated inward strongly, with the elbow slightly flexed, the forearm pronated so that the palm faces backward and outward and the wrist and fingers flexed. The most marked muscular atrophy is in the supra- and infra-spinati and deltoid. The pectoralis major and the subscapularis unopposed by any outward rotator keep the arm so strongly rotated inward that the head of the humerus is constantly stretching the posterior portion of the capsule. This stretching is increased by the backward and the downward pull of the latissimus dorsi. The result is a contracture of the pectoralis major and a gradual yielding of the weak posterior portion of the capsule. A backward displacement inevitably follows. The stronger anterior portion of the capsular ligament and the coracohumeral ligament, which at first prevented any forward dislocation, are not developed normally, and together with the contracture of the pectoralis major, hinder the rotation of the arm outward and the replacement of the head of the humerus in the glenoid cavity. Secondary bony changes may occur both in the glenoid cavity and in the head of the humerus. From disuse of the arm, lack of growth is common. It is possible that in some cases more or less recovery of power may occur in the deltoid and outward rotators, even after considerable displacement of the head of the humerus has occured. This is probably the manner of production of most of the so-called congenital dislocations of the shoulder, which is, therefore, usually a misnomer.

There are three classes of infantile dislocations of the shoulder. The first includes the true congenital dislocation, where the lesion is due to a true lack of development during intra-uterine life of the glenoid cavity and the head of the humerus, analogous to the congenital dislocation of the hip. This form of dislocation, however, is extremely rare, and many cases reported as congenital dislocations are probably in reality paralytic dislocations. While a lack of development in the acetabulum is the most frequent congenital defect in the pelvis, in the shoulder girdle congenital defect of the glenoid is less common than other malformations, such as absence of the clavicle, congenital elevation of the scapula, exostosis of the scapula, or defect of its lower portion. Lack of development in later childhood or in adult life cannot in any sense be taken to indicate that the dislocation is truly congenital, for in severe cases of obstetrical paralysis lack of development is common.[1] The association of paralysis with cases regarded as congenital dislocations should lead to the suspicion that the paralysis was the cause of the dislocation, and especially should this be suspected in cases in which there is reason to believe that the paralysis arose from trouble during delivery. If the cases reported as congenital dislocations of the shoulder are studied in this way, a large majority of them must be looked upon as probably of paralytic origin.

Another class of infantile dislocation is the traumatic. It is undoubtedly possible that this may be produced during delivery. Experiments and clinical experience, however, both show that this must be an extremely rare occurrence, simply because any violence sufficient to force the head of the humerus through the capsular ligament would almost invariably produce other injuries which would allow the shoulder-joint itself to escape.

A vast majority of the cases of infantile shoulder dislocations must be regarded as paralytic. The displacement may have been aided by rupture or stretching of the posterior part of the capsule at birth, but they are not true dislocations in the sense that the head of the humerus has passed through a rent in the capsular ligament. They are due to a gradual yielding of the ligament under a constant unopposed muscular pull in one direction.

Before speaking of treatment something should be said regarding prophylaxis. Traction is the cause of obstetrical paralysis. Of course it is often absolutely necessary to use extremely severe force in delivery where the choice must often lie between injury to or death of the child. There are certain times, however, when traction directly on the shoulder may be avoided. Particlarly in delivering an after-coming head, the pull may be exerted on the pelvis and chest rather than on the shoulders. In delivering the shoulders after the head is born, direct traction is much more apt to cause paralysis than is the freeing of the shoulders by insertion of a finger in the axilla,—a maneuvre likely of course to fracture the humerus. This accident, however, is far less serious than a paralysis. The suggestion of Walton that the second stage of labor is to be hastened should be limited by the other rule that it should not be shortened by any measure producing traction on the shoulders.

After the injury is done, support for the arm is essential. Thus further dragging on the stretched nerves or separation of their torn ends is prevented, the stretched ligaments are supported and the muscles are given a chance to recover their tone. The muscles should be protected from undue stretching just as in the early stages of infantile paralysis.

Thus for a time further harm is prevented. Later, massage and electricity have their uses. By these simple measures, or even without treatment recovery will occur in probably a considerable majority of the cases. The obstetricians thus regard obstetrical paralysis rather lightly, while the neurologists and orthopedic surgeons, who only see those cases which do not recover, regard the prognosis as bad. This difference is due probably to the varying degree of injury to the nerves; in one case simple stretching, in another a rupture of certain fibres of a nerve, and in the most severe possibly a complete tearing apart of the whole nerve. In cases not improving decidedly within the first six or eight weeks of life a serious injury to the nerves is to be regarded as probable, and consequently the outlook for marked im-

[1] Une Endémie de Paralysies Radiculaires Obstétricales. Guillermot: Annales de Gynécologie et d'Obstétrique, 1897, vol. xlvii, p. 35. An interesting series of cases occurring in the practice of one midwife, and probably usually due to difficulty in delivering the head after version before full dilatation had occurred.

provement is poor, although improvement has occurred after years.

It is a question whether in certain cases the injury cannot be repaired by surgical interference. The greatest obstacle to any successful nerve suture is that in all probability the nerves are torn by individual fibres as a hemp rope tears, not directly across at any one point. Furthermore, after several weeks there would probably be the greatest difficulty in recognizing in the small nerves of the baby any abnormality without considerable manipulation. And during the interval of waiting for improvement to occur, an ascending degeneration of the torn fibres would probably have occurred which would interfere with a restoration of function, even after approximation of the torn ends. Exploration is possible, however, even in small babies.

In the lower part of the posterior triangle of the neck the upper brachial plexus is comparatively easy of access. It lies back of the sternomastoid, above the omohyoid, in front of the trapezius. The scalenus anticus and the sternomastoid protect the great vessels and the phrenic nerve. The spinal accessory nerve is considerably behind the plexus. The subclavian vessels, thoracic duct and several small arteries running across the neck are all below the omohyoid.

The external jugular vein and the branches of the cervical plexus which wind around the posterior border of the sternomastoid are in danger. The difficulty in reaching the upper cords of the plexus lies chiefly in the shortness of a baby's neck. The outlook for successful interference, however, is doubtful. In one case, in a baby of six weeks, I have cut down on the plexus, but found nothing more that a rather soft spot just below the junction of the fifth and sixth roots. The child died of pneumonia two weeks after operation. In the older cases where dislocation has occurred probably little is to be hoped from nerve suture, although exploration is justifiable.

Leaving aside the possibility of any radical cure of the condition through repair of the nerve injury and consequent restoration of power in the paralyzed muscles, several palliative measures are to be considered. The condition always present and the one for which relief is most often sought is the inward rotation of the arm. The inability to elevate the arm and the other paralyses vary considerably in degree. For the relief of the inward rotation, stretching or section of the contracted pectoralis major is necessary. By means of plaster bandages applied with the forearm flexed to a right-angle and the arm rotated outward with the elbow at the side, it is a simple matter in the course of a few days or weeks to overcome the inward rotation and by direct pressure to bring the head of the humerus back into the glenoid cavity, if it is dislocated. It is possible that in a few cases rest of the over-stretched outward rotators may thus enable them to recover their tone and bring about some improvement. Relapse will almost surely occur, however, unless systematic passive motion and massage is used, aided by some orthopedic apparatus to check inward rotation.

In the more marked cases of longer duration section of the contracted muscles will cause a considerable improvement, but here again systematic after-treatment is essential. Several cases, among them one of my own, thus operated upon have been somewhat benefited.

The operative procedure of Phelps[8] consists in deepening the glenoid cavity, paring off a portion of the head of the humerus and stitching up the lax posterior portion of the capsular ligament. His procedure is based upon the belief that the dislocation results from a fracture of the posterior portion of the glenoid cavity occurring at birth. In one case in which I opened and explored the shoulder-joint in a boy six months old with a typical paralytic dislocation I found no evidence of malformation or fracture of the glenoid or head of the humerus. Stitching up more snugly the posterior ligaments caused slight improvement, although in his case systematic stretching of the anterior muscles probably accounted largely for any benefit obtained. Previous section of the contracted pectoral muscle should be advised.

In certain rare cases there is a marked laxity of the whole of the capsular ligament and an unusually extensive muscular paralysis, allowing the arm to drop downward. Here a shortening of the ligaments in order that the head of the humerus may be brought up into its normal relations will be of benefit. In all cases, however, in which the joint is opened, particularly where any portion of bone or cartilage is excised, the formation of adhesions is to be considered. Of course, in this manner, motion in the shoulder-joint is limited, but this very limitation of motion may still be a means of increased functional usefulness in the arm. In fact, in certain cases, where the paralysis is extensive, an arthrodesis of the shoulder-joint may greatly improve the condition, through enabling the arm to be moved by movements of the scapula.

Another measure to be considered in overcoming the inward rotation of the humerus is a linear osteotomy of the upper portion of the shaft of the humerus, with union of the bone in a position of outward rotation. Another possibility to be considered in overcoming the inward rotation is a transference of the insertion and consequent change in function of the latissimus dorsi. After the section of the pectoralis major, which is the operative procedure usually demanded, the latissimus dorsi might be exposed and cut close to its insertion along the inner edge of the bicipital groove. It might then, by means of a posterior incision, be reached and drawn back to be sutured to the humerus under the posterior border of the deltoid immediately below the insertion of the teres minor and above the origin of the external head of the biceps. In this manner the pectoralis major would be lengthened and the latissimus would be changed from an inward to an outward rotator of the arm, in a manner similar to that in which Tubby, by changing the course of the pronator radii teres, converts it into a supinator of the forearm. Some such measure as this would, if successful, overcome the great obstacle to permanent reduction.

In conclusion I wish to emphasize these points:

True congenital dislocation of the shoulder, that is, defective development of the scapula and head of the humerus, is of extremely rare occurrence.

True traumatic dislocation of the shoulder at birth or in early infancy is of extremely rare occurrence.

Obstetrical paralysis, which, as has long been recognized, is of Erb's type, is due probably almost invariably to a stretching and in some cases a rupture of the two upper roots of the brachial plexus, as is proved by anatomical study.

[8] Transactions American Orthopedic Association, vol. viii, p. 239.

Obstetrical paralysis is usually recovered from entirely in the course of a few weeks or a few months. If recovery does not occur within this period the prognosis is very much more serious, although improvement may occur even after the lapse of many years.

After an infant's arm has been held in the position of inward rotation for some months the posterior part of the capsule becomes so stretched as to permit the head of the humerus to slip out of the glenoid cavity posteriorly, while the anterior portion of the capsule and the pectoralis major are shortened. This backward subluxation is always made easier by the relatively small size of the glenoid cavity in infancy. It may be made easier by a tearing and stretching of the posterior part of the capsular ligament through the same trauma which stretched the upper cords of the brachial plexus.

A dislocation of this sort is easily reduced by measures which stretch the inward rotators of the arm, but when thus reduced it is held in place with extreme difficulty, because the cause which originally produced the dislocation, that is, the unopposed action of the inward rotators, is still present.

Any abnormality in the shape of the head of the humerus or in the glenoid in a case accompanied by paralysis or lack of development of the deltoid and supra- and infra-spinatus muscles is probably secondary to the paralysis, and if accompanied by a dislocation is not to be looked upon as the primary cause of the dislocation. Lack of bony development of a paralyzed arm may become very marked after the lapse of years, and this lack of bony development is not in any way to be regarded as proof of a congenital defect.

All early cases of obstetrical paralysis are to be treated by sling or bandage which will support the paralyzed muscles and prevent dragging on the ligaments and injured nerves.

In cases of obstetrical paralysis which persist without improvement there is reason to hope that surgical intervention looking to a union of the torn ends of the fifth and sixth cervical roots at a point from a quarter to three-quarters of an inch from their emergence from the canal may be of benefit.

The subluxation resulting from the paralysis is to be treated by stretching or section of the contracted muscles and ligaments, by osteotomy, arthrodesis, or muscle transfer, according to the conditions present in each case.

STEAM IN THE TREATMENT OF CHRONIC, HYPERPLASTIC, AND SENILE ENDOMETRITIS, PUTRID ABORTION AND PUERPERAL SEPSIS.[1]

BY F. W. JOHNSON, M.D., BOSTON,
Visiting Gynecologist, Carney and St. Elizabeth's Hospitals.

When I went on duty at the Carney Hospital in the fall of 1898 I found Dr. Malcolm Storer had been and was using steam in the treatment of the various forms of uterine hemorrhage. This method of treatment appealed to me, and I began its use at once in the treatment of chronic endometritis and menorrhagia.

Concerning this method Prof. A. Duhrssen thus writes:[2] "The method of arresting hemorrhage by steam was first employed by Sneguireff, of Moscow, in 1894, for profuse hemorrhage during the removal of an echinococcus cyst from the liver. Since then experiments have shown that parenchymatous organs can be incised almost bloodlessly, and that hemorrhage from arteries of the size of a dog's femoral can be quickly arrested by a steam jet.

"The technique is simple. A fenestrated uterine catheter is joined by a gutta-percha tube to a small boiler. The steam issuing from it should be at 212° F. Higher temperatures are advocated by some, but the author has never used them, except in experiments on animals. In this way dangerous uterine hemorrhage can be arrested permanently and painlessly without an anesthetic; and serious operations, for instance, hysterectomy for fibroid tumors, may often be avoided.

"The details of the procedure differ according to the age of the patient. If the steam is allowed to act for two minutes, exfoliation of the uterine mucous membrane follows, either *en masse* or piecemeal. A raw surface is left which forms adhesions, which cause obliteration of the cavity and subsequent atrophy of the uterus, and hemorrhage is cured as certainly as though the uterus had been removed. In order to exclude cases which are unsuitable for this treatment, such as malignant tumors or placental remnants, the cervix must always be dilated first. An important detail is that the instrument, when it passes through the cervix, must be encased in a drainage tube, for otherwise the heat may damage the cervical walls, and be followed by obliteration of the cervical canal and hematometra.

"Cases in which this treatment is indicated are exhausting floodings between the ages of forty and fifty, whether caused by chronic metritis, by abnormal friability of the walls of the uterine vessels, or by small interstitial myomata. In this last case the steam probably produces atrophy of the myoma, as well as of the uterus. Where it is required to arrest abnormal uterine hemorrhage without causing obliteration of the uterine cavity, as in young women with too profuse menstruation, the steam must not be allowed to act for more than a quarter of a minute (Sneguireff says one minute, which is certainly too long), and the process should not be repeated until after the next menstrual period. The application of steam for a quarter of a minute successfully sterilizes septic endometritis in puerperal fever, and the raw granulating surface left offers an excellent barrier against the further entry of bacteria into the circulation. Good results have also been obtained in subacute and chronic gonorrhea, and the author suggests its use as an abortive treatment for acute cases.

"If carried out properly the treatment is quite harmless, and has no disadvantages."

Dr. Alexander Rovinsky wrote me that Sneguireff, together with Blogovolin, had experimented on animals and had come to the following conclusions: (1) Desired portions of the liver could be excised without loss of blood, the animals surviving; (2) any part of the spleen could be cut out without loss of blood; (3) whole lobes of lungs can be removed without any loss of blood; (4) the same applies to the kidney; (5) also to some extent to the brain; (6) it is possible to stop the bleeding from the spongy portions of bones; (7) the marrow of the bone coagulates and the regeneration of the bone takes a normal course;

[1] Read before the Suffolk District Medical Society, Section for Obstetrics and Diseases of Women, November 22, 1899.
[2] Klinische Wochenschrift.

(8) almost the whole cornu uteri may be taken out of the dog without bleeding; (9) the femoral artery of the dog, when cut transversely or otherwise, will not bleed after the application of steam; (10) bleeding from skin and muscles ceases immediately; (11) wounds subjected to the action of steam heal *per priam intentionem*; this last was observed not only on the experimented animals, but also on human beings.

Sneguireff has applied steam successfully as a hemostatic in the following operations: (1) In five cases of resection of the knee-joint, without any preliminary use of the bandage, or any employment of ligatures or forceps; (2) in extirpating a carcinomatous mamma under the same conditions; (3) for the removal of fatty, cancerous and other tumors of the skin; (4) in amputation of the cervix; (5) in resecting bones and in sequestrotomies: (6) in abscesses to deodorize and to promote filling up of the abscess cavity; (7) in various sinuses and fistulæ (especially of a tuberculous nature).

Sneguireff, in 1895, was first to suggest the use of steam in the uterine cavity. He spoke of steam as a styptic, even strong enough to stop a dog's femoral. In 1895 Pincus was led to try it in gynecology by Sneguireff's article. He used the ordinary kettle of an inhaling apparatus with a safety valve. A male catheter with a slight curve and three lateral windows to aid in the escape of the steam was used in conducting the steam inside the uterus. He states that it is a *sine qua non* that the uterus should be perfectly movable if the operation is to be done without ether. In 1895 he used it in a few cases with good results.

Panecki had a similar experience in 1896. Kahn (1896) in his early trials used steam at 100° C. for two minutes; later 115° for fifteen seconds to one minute. In his experience he found that the more energetic the treatment, the better the results. It is generally painless. He used it mostly post partum. If in such cases the uterine walls are thin, only low pressure is admissible. It seems to do good in *incipient* inflammation of the appendages, but should not be used when actual pus is present. If the products of conception are retained, they should first be removed. He used it in nine puerperal cases. He claims that steam in the uterine cavity has (1) no disadvantageous sequelæ and causes practically no pain; (2) quiets sensitiveness; (3) starts good contractions; (4) deodorizes; (5) sterilizes; (6) through shutting off blood and lymph vessels by coagulation of albumin, it affords a roof for new granulations to form under.

Pincus, in 1897, reports several cases in the treatment of putrid abortion. He emphasizes that in puerperal cases it must be used only when appendages are free. It is especially valuable in cases of habitual abortion, as it removes the diseased endometrium which very likely is the cause of the abortion. At that time he used a wooden speculum to guard the vagina. He uses it without paying any attention to possible retained membranes. He regards it, to a certain extent, a specific in the treatment of putrid abortion. It was not found valuable in bleeding submucous fibromas or other causes that render the inner surface of the uterus irregular. Examination of specimens showed that the action was most vigorous in the immediate neighborhood of the canula.

Schick (1897) used hot water instead of steam. He used it boiling with certainty that by the time it reached the uterus its temperature had dropped to 80° C. or 85° C. He used it one-half to two minutes. He used it in four cases, all under ether.

In 1897 Sneguireff had used steam 400 to 500 times without the slightest bad effect. In cases occurring at the menopause, if the bleeding cannot be stopped otherwise, he advises using the steam longer than one minute. He advises against the use of steam, if there is any disease of the adnexa. Steam should be delivered in the uterus at about 100° C.

In 1898 Pincus further remarks about vaporization and vapocauterization: "My communications concerning the value as a therapeutic agent of hot aqueous steam in gynecology and obstetrics have attracted much attention on the part of my colleagues, if I can judge by the number of communications I have received from all parts of the world in reference to it. But my own service in the matter is only a very modest one, for, as I have already carefully stated, it was only through the reading of Sneguireff's communication as to the styptic effect of hot steam that I was led to introduce its use in gynecological and obstetrical therapeutics."

Pincus has got up a very complete apparatus, which is described and pictured in the *Centralblatt für Gynecologie*, 1898, page 256. In this machine he controls both the pressure and the temperature of the steam. He thinks many of the failures have probably been due to not sending the steam into the uterus hot enough. He generally keeps patients in bed a week. There is almost always more or less discharge, which seldom amounts to much. The odor in septic cases almost always stops. He still sticks to his view that tender appendages and a stricture of the cervical canal are contraindications. He has no fear that steam will get into the tubes, but if the tubes are diseased harm could easily be done by the vigorous contractions of the uterus that are set up. In general terms he regards a very rigid cervix as a contraindication. Warns against veiling malignancy by means of vaporization. He says steaming is of especial value in the bleeding of the climacteric, not depending on malignant disease, and leucorrheas following the menopause. In one obstinate case he used it at 119° C. for two minutes, with the complete destruction of the uterine canal, but cured the patient just the same. He has used it in 18 post-climateric floodings, with good effect in 13. Was obliged to repeat the steaming in two cases. Also used it one minute at 100° C. to 105° C. in seven cases of metrorrhagia and subinvolution, with five successes. He does not believe in using it in submucous fibroids on account of the danger of suppuration. Has used the steam in a large number of cases of endometritis with good results. Sometimes he uses the steam and sometimes the vapocautery. Cured three cases of gonorrheal endocervicitis. He found the steam did no good in a case of puerperal general sepsis.

Hollander, in 1898, showed his apparatus for the use of hot air instead of steam. Can get by it three times as much heat as by steam; can measure it better and apply it more exactly.

Baruch (1898) reports a case of complete atrophy of the uterus following steaming. "Girl, age twenty-seven, was steamed once as an out-patient by a female M. D. Never any menses afterwards, with symptoms of the menopause. Uterus, when examined several months afterwards, was found tiny in size.

Again quoting from Pincus (1898): "By this time

the apparatus has proved its worth. Now it will be only a great exception that one will be obliged to remove a uterus for a hemorrhage at the menopause. Further experience leads me to suggest the following: (1) The cervix should be protected in every case. It is a necessity if the treatment is to last longer than one-half minute. As far as that goes, time begins to show me that in most cases half a minute is quite enough, especially if previous to using the steam you carefully wipe out the uterus with a Playfair sound. If there is much detritus in the uterus, steam should be played in for thirty seconds, then the clots removed and the steam reapplied for thirty seconds more; (2) there should be no repetition of the steaming until complete regeneration of the mucous membrane has taken place; (3) steaming for endometritis should be done in the few days before menstruation, or after it, and never during."

Kahn (1898) writes: "If you want to produce a deep effect use low temperature a long time, and if superficial a high temperature a short time, that is, bleeding of the menopause *versus* puerperal conditions. In puerperal cases I use even up to 112° C. for even three to four minutes, depending on intensity of affection." He reports a case of pregnancy and labor following one steaming out. "The steam tube should not be pressed against the fundus, as you may get a perforation later on."

Weiss (1898) reports the case of a girl, age nineteen, where steam at 100° C. for three or four minutes was used for metrorrhagia (not a puerperal case). There followed complete obliteration of the uterine cavity and severe symptoms of the menopause. He has collected three cases of obliteration and two of stenosis of the cervix following the use of steam, a large number considering how new the process is and how little used as yet.

For three years Fenomenow has used steam where the uterus was to be opened. Where the uterus was septic he has often steamed for several minutes to ensure its disinfection before removal. He even steams before vaginal hysterectomies and before morcellation.

Pincus (1898) gives his views on the present state of steaming as follows: "Atrophy of the uterus with obliteration of the canal cannot be called a 'mischance'; it is inexcusable. Steaming is of inestimable value in inoperable carcinoma of the fundus. In the treatment of subinvolution I regard it as something we cannot do without. It may also be of value in producing artificial sterility, if desired."

Pincus makes the rule to use the steam as short a time as possible. Fifteen seconds is generally enough. Thirty seconds is the maximum. In young people thirty seconds is to be regarded as too much. It is better to repeat after the mucous membrane has had a chance to regenerate. The temperature of the steam inside the uterus should range between 102° C. and 110° C. The rule is, the shorter you are to work the higher must be the temperature. The quicker you work, that is, the less the cooling off after you shut off the steam in the catheter, so much the prompter is the effect. In a recent case he used 109° C. for only eight seconds and stopped a vigorous hemorrhage entirely. In old women, when very likely you desire to obliterate the uterine cavity, he uses it about two minutes at 105° C. to 110° C. and repeats if necessary.

After experimenting for a long time I have decided that the following method of doing the operation gives me the best results. The ordinary steam throat atomizer is used for generating steam: A hard-rubber tube eight inches in length, the size of a No. 18 French bougie, conically pointed at one end, is connected with boiler by soft-rubber tubing. The hard-rubber tube is detachable and is boiled in the soda solution with the instruments. The external genitals are washed with soap and water, then with permanganate-of-potassium solution and oxalic-acid solution; finally rinsed off with normal salt solution. The vagina is treated in the same way. After dilating the cervix, wipe dry with sterile gauze the cervical and uterine cavities. Introduce the small-size uterine speculum and through it steam body and cervix thirty seconds. Remove uterine speculum, wipe dry with sterile gauze the cervix and body, and steam again for thirty seconds. The patient is kept in bed from four to six days. Short douches are given night and morning. The steam as it leaves the boiler is 212° F., but inside the uterus the temperature varies from 192° F. to 212° F., dependent upon the amount of moisture in the uterus. With a dry uterine cavity the self-registering thermometer would indicate 212° F. There is no danger of burning too deeply if the steam is used as above described.

Unless I wished to obliterate the uterus I should not consider it permissible to use the steam under pressure or to use it longer than one minute. In puerperal cases the curette makes raw healthy as well as diseased surfaces, while the steam can be used without doing any mechanical injury. The steam is safer and more thorough than the curette. We all know from experience repeated over and over again how very difficult it is to curette smoothly the inside of the uterus. Islets of tissue are apt to be left here and there, especially at the fundus and in the horns. The steam uniformly reaches every part of the uterine cavity, and there is no danger of it escaping into the tubes, if used as I have described.

It was by having steamed uteri examined by the pathologist that the proper *modus operandi* could be determined upon. To work up from a comparatively short exposure of the uterine cavity to steam (212° F. as it leaves the boiler), examining the uteri from time to time, until the examination showed that the endometrium was destroyed almost down to the muscular layer, seemed the safer plan, then drawing conclusions from the clinical results. I felt safe in stopping just short of the muscular tissue in cases of chronic endometritis, hyperplastic endometritis, etc., than to run any risk of *burning* the muscular tissue or of destroying the glands and thus cause cicatricial tissue where no endometrium would be produced. Where there is suspicion of malignant disease, tissue for microscopical examination should be removed with the curette at the time of steaming. The tissue destroyed by the steam begins to come away in seven to twelve days. It may come in small pieces or in quite large junks, like the specimens shown. Since receiving Dr. W. F. Whitney's report of the examination of the first uterus sent him, I have steamed through the smaller uterine speculum and have used the steam as above described. The smaller speculum would offer less chance of escape for the steam, consequently there would be more heat inside the uterus and the cervical canal would be just as well protected.

DR. WHITNEY'S REPORT.

"I have finished the examination of the four uteri which you have cauterized by steam, and as far as I can determine, in none of them has the mucosa been entirely destroyed through its entire thickness. The action in all seems to be fairly uniform throughout the entire canal, although in No. 3 (January 21, 1899) it failed to reach the bottom of the cornu at the fundus. In No. 4 (January 25, 1899), on the whole, the action seemed to be the deepest, while in No. 3 (January 21st) it seemed to be the least. In none was there much of the cervical lining left, whether destroyed or rubbed off I cannot say, but there was no evidence of any action on the muscular tissue. In all the action was most marked at the fundus, but as the endometrium was thicker there only about one-half its thickness was destroyed. Of course the cells may be killed more deeply than the microscope will show, as their vital function may be gone although the nuclei still stain and the shape of the cells is unaltered. But as far as any physical evidence goes, the action has in no case extended more than through three-fourths of the thickness of the endometrium, and then without absolute uniformity."

This report was very satisfactory, in that it showed the destruction did not go into or even quite down to the muscular tissue. I was aiming to get live steam hot enough inside the uterus to cause exfoliation of the entire endometrium. The effect on the edometritis will show this. If it is desired to cauterize into the muscle, as in senile cases of hemorrhage or endometritis, it would simply be necessary to allow the steam to escape inside the uterus for two minutes or more.

I have here tabulated 31 cases. Previous to using steam these would have been curetted. Each case was looked up two or more months after the steaming to ascertain what effect it had had on the endometritis and the menstruation.

In addition to the above, I have used it in one puerperal case, curetting just before using the steam. The uterus had been curetted twice by the attending physician. She had been septic for three days. Pulse and temperature were high. There was a profuse and offensive vaginal discharge, she had had one rigor and there was phlegmasia alba dolens on the left. She got no worse after the steaming, remained about as she was for thirty-six hours, and then began to improve.

During the past year steaming was done in a great many cases where other operations were performed, and it was not always possible to say how much the other operations contributed to the relief of symptoms. Consequently, in these 31 cases, I have selected as much as possible those who were alone steamed.

CASE I. K. McM., twenty-four, single. Dysmenorrhea for the past six months; constant leucorrhea; frequent micturition, with scalding. Consumptive family history. Diagnosis: Chronic endometritis and chronic urethritis. Uterus curetted for specimen, then steamed. A solution of nitrate of silver applied to the urethra. No tubercle bacilli found in the scrapings. Has been unwell five times since going home. Has had no dysmenorrhea and there is no leucorrhea.

CASE II. J. H. C., twenty-four, married. Backaches; severe dysmenorrhea; leucorrhea since childhood. Diagnosis: Chronic endometritis. Uterus steamed in February, 1899. Has menstruated since then without pain, and has been absolutely free from all backache and leucorrhea since the operation.

CASE III. W. H. H., thirty, married. One child, eleven years ago. Dysmenorrhea during the first day of sickness; abundant leucorrhea, requiring the use of a napkin; at times considerable hemorrhage from the bladder, and smarting and burning during micturition. Diagnosis: Chronic endometritis and chronic urethritis. Uterus steamed in May and urethra painted with nitrate of silver. The injection of the urine into guinea-pigs excluded tubercular disease, which was strongly suspected. No dysmenorrhea, no leucorrhea, and no trouble with micturition since the operations. The patient is now three months pregnant.

CASE IV. H. R., fifty-one, married. For four years very profuse leucorrhea, at times very irritating; obliged to wear a napkin most of the time. Diagnosis: Senile endometritis. Four months after the steaming there was a little leucorrhea, but it was not irritating. Advised a second steaming, which was done November 15, 1899; the uterus was steamed two minutes.

CASE V. A. A. Q., twenty-five, married. Menorrhagia, severe dysmenorrhea; leucorrhea for four years. Some time ago had scalding micturition for two months; dysmenorrhea, requiring the use of morphine. Diagnosis: Chronic endometritis. Uterus steamed. Two months after the steaming there has been no leucorrhea and no pain during menstruation.

CASE VI. R. P. E., thirty-one, married. Leucorrhea since puberty; a show of blood every two weeks for last five months. Diagnosis: Chronic endometritis. Uterus steamed. Been unwell three times since the steaming; first time went three weeks and five days; since then has been regular; almost no leucorrhea.

CASE VII. E. B., twenty-eight, married. Menorrhagia; the amount has doubled in the past two years; leucorrhea. Diagnosis: Hyperplastic endometritis. Uterus steamed. Been unwell twice since the steaming; flowed four days, formerly seven to ten, and had no pain; no leucorrhea.

CASE VIII. T. W. F., forty-one, married. Been flowing constantly for fourteen days; leucorrhea for one year; at times it is bloody. Diagnosis: Three polypi projecting from cervix; hyperplastic endometritis; uterus large. Scrapings removed for pathologist and the uterus steamed. First menstrual period occurred twenty-five days after the steaming; used twelve napkins; no pain. Menstruation returned in twenty-eight days; used eight napkins and was through in five days; no pain. Between and since these menstrual periods there has been scarcely any leucorrhea and that not bloody. Dr. W. F. Whitney reports that it was a case of polypoid glandular hyperplasia.

CASE IX. B. R., thirty-seven, single. Constant leucorrhea with backache and dragging down; dysmenorrhea with menorrhagia (soaks twenty-five to thirty napkins). Diagnosis: Chronic endometritis. Uterus steamed. No improvement in the menorrhagia; relief of the dragging down feeling and diminution in the amount of leucorrhea. Advised steaming again.

CASE X. H. C. Q., thirty-two, married. Gonorrheal vaginitis, endometritis and urethritis of some weeks' duration. May 5, 1899, uterus steamed; vagina swabbed with Churchill's tincture iodine; nitrate of silver applied to dilated urethra.

May 30th, returned with a fresh attack. Treated as above, with complete relief.

CASE XI. M. S., twenty-four, single. Constant leucorrhea with backache; dysmenorrhea. Diagnosis: Chronic endometritis. Uterus steamed. No dysmenorrhea or leucorrhea since the operation.

CASE XII. E. Q., sixteen, single. Leucorrhea with backache and severe dysmenorrhea. Diagnosis: Chronic endometritis. Uterus steamed. Been unwell twice since the steaming; no pain; no leucorrhea.

CASE XIII. M. D., thirty-seven, married. Had four abortions at three months from July, 1895, to December, 1898; constant white thick leucorrhea. Diagnosis: Chronic endometritis. Uterus steamed. No leucorrhea since the

steaming. It would now be very satisfactory if she would become pregnant and not abort.

CASE XIV. L. K., twenty-five. Thick vaginal discharge, at times offensive, for a long time. Diagnosis: Debility, retroversion and chronic endometritis. The uterus was steamed and an Alexander operation done. Two months and a half after the steaming she reported that there had been no vaginal discharge for some weeks after the steaming. Then without cause it began, but it was not as bad as formerly. Two months and a half after the first steaming, and a few days after a menstrual period, steam was again applied. The cervix was found patulous, the internal os easily admitted a Sims's sound and there was no indication of cicatricial tissue. There has been no leucorrhea since the second steaming.

CASE XV. C. E., married four years. Dysmenorrhea. Profuse, thick, yellow vaginal discharge. Diagnosis: Chronic pelvic peritonitis and chronic endometritis. On opening the abdomen a condition was found demanding hysterectomy. On examining the uterus the endometrium was found everywhere of a brownish-black color. The fundus and horns had been thoroughly steamed.

The uterus was sent to Dr. W. F. Whitney, and the following is his report: "I have examined the uterus cauterized with live steam, and find in the cervix, where the mucosa was very thin, that apparently the whole thickness had been killed, in the middle of the body about three-quarters of the thickness, and in the depths of the fundus about one-half the thickness. The action was very uniform everywhere, but I should not think that the length of time was sufficient to destroy the mucosa throughout. Of course, the action may go deeper than the microscope shows, but all that I can judge by is the depth to which the blood corpuscles and cells are altered."

After Dr. Whitney's report was received the uterus was steamed for a longer time.

CASE XVI. A. E. W., twenty-three, single. Severe dysmenorrhea; considerable leucorrhea. Diagnosis: Chronic endometritis; hemorrhoids. Uterus was steamed. Three months after leaving the hospital had menstruated twice without pain. There was no leucorrhea.

CASE XVII. K. T., twenty-five, married seven years and never pregnant. Has had repeated attacks of peritonitis and frequent and painful micturition. Severe dysmenorrhea and considerable leucorrhea. Diagnosis: Retroversion and chronic endometritis. Uterus steamed; left tube and ovary removed, part of the right ovary resected and the uterus suspended. Three months after the operation had menstruated twice, and instead of flowing ten to fourteen days she flowed seven days the first period and six the second. During these periods there was but slight dysmenorrhea.

CASE XVIII. M. G., seventeen, single. Neurasthenic; severe dysmenorrhea; profuse thin, odorless vaginal discharge. Diagnosis: Retroversion with adhesions and chronic endometritis. Uterus steamed; portions of both ovaries resected and the uterus suspended. Menstruation did not appear for a month and a half. She used in all but five napkins; before the steaming used eighteen to twenty. Had severe dysmenorrhea; no leucorrhea.

CASE XIX. L. R., thirty-one, single. Severe dysmenorrhea; some leucorrhea. Diagnosis: Retrocession; shortening of the uterosacral ligaments; chronic endometritis. Uterus steamed; uterosacral ligaments cut and uterus suspended. Menstruated while in the hospital with but little pain. Menstruated one month after getting home with scarcely any dysmenorrhea; no leucorrhea.

CASE XX. A. F., twenty-seven, single. Menorrhagia; constant thin, yellow vaginal discharge. Diagnosis: Retroversion, bound down by adhesions and chronic endometritis. Owing to the profuse menorrhagia the uterus was curetted and then steamed. The right tube and ovary were removed, part of the left ovary resected and the uterus suspended. Four months after the operation she had been unwell three times; flowed five days and used about eight napkins. Has had slight amount of leucorrhea.

CASE XXI. E. O. B., twenty-five, single. Neurasthenic; dysmenorrhea; menorrhagia; thick, yellow vaginal discharge with offensive odor. Diagnosis: Retroversion and chronic endometritis. Uterus steamed and an Alexander operation done. Two months after the operation she had been unwell twice. There was great improvement in the menorrhagia, but she still had dysmenorrhea and leucorrhea.

CASE XXII. E. B. H., twenty-six, single. Leucorrhea began thirteen months ago as a yellowish discharge, which soon became greenish in color. Irritation and soreness soon began about the vulva, accompanied with scalding during micturition; obliged to wear a napkin; severe dysmenorrhea. Diagnosis: Endometritis, vaginitis and urethritis. Uterus steamed and Churchill's tincture iodine applied to the dilated urethra. Three and a half months after the steaming she had been unwell twice; flowed about as formerly; some dysmenorrhea, but not as much as formerly; none during the flow; diminution in the amount of leucorrhea.

CASE XXIII. B. F., twenty-eight, single. Severe dysmenorrhea the first day, confining her to bed; profuse leucorrhea. Diagnosis: Anteflexion of uterine body; undeveloped uterus; retrocession; chronic endometritis. Uterus steamed. Been unwell twice since steaming; flowed freely and had no pelvic pain. Before the operation flowed but little, and had severe dysmenorrhea; no leucorrhea.

CASE XXIV. A. R., twenty-eight, married. Sterile; considerable leucorrhea; no dysmenorrhea until September, 1898. Diagnosis: Tumor on right side of uterus anteriorly; chronic endometritis. Uterus steamed; left tube and ovary removed; small fibroid enucleated. Been unwell once since the steaming; flowed as formerly, but had no pain; has no leucorrhea; freedom from all pain.

CASE XXV. H. D., forty-five, single. Epileptic for thirty years; considerable leucorrhea; dysmenorrhea. Diagnosis: Retroversion; cystoma on the left side; chronic endometritis. Uterus steamed; cystoma removed and uterus suspended. Been unwell once since the operation; no improvement, except some diminution in leucorrhea.

CASE XXVI. C. E. W., forty-two, married. Slight leucorrhea. For the past ten years has had backache when unwell. Diagnosis: Retroflexion; a mass on the left side of the uterus; chronic endometritis. Uterus steamed. Hysterectomy was then done. Specimen sent to Dr. W. F. Whitney. This was the second uterus sent to Dr. Whitney.

CASE XXVII. M. McC., twenty-nine, married six years. Has had one child and two abortions; last abortion three years ago. Six weeks ago began to flow, and has flowed more or less ever since; previous to six weeks ago had not flowed for months, as she was nursing her child; white and thick vaginal discharge, requiring a napkin. Diagnosis: Retroflexion of a large soft uterus; chronic endometritis. Uterus steamed; uterus suspended. No flowing since the steaming (over two months); much leucorrhea; uterus of normal size and in perfect condition. Advised steaming again.

CASE XXVIII. F. B., thirty-two, married one year; one child; no abortions. For six weeks sharp, crampy pain in left ovarian region; backache; white, watery vaginal discharge; some dysmenorrhea. Diagnosis: Chronic endometritis; uterus pushed to the right; cystoma of the left ovary. Uterus steamed; cystoma removed; uterus suspended. Been unwell twice since the steaming; first time flowed one-half day; flowed a very little for a few hours; "had an ache just below the navel." Second time flowed two days; soaked five napkins; no pain; has absolutely no leucorrhea.

CASE XXIX. C. C., thirty-three, married eighteen years; three children; no abortions. Constant leucorrhea; for three years has had more or less dull pain in the region just below the right kidney; pain in the left ovarian region. Since October has noticed swelling in the right iliac region. Uterus steamed; cysts in right ovary punctured with cautery; uterus suspended; adhesions about the gall-bladder broken up. The right kidney, which was very movable, was fastened by securing its capsule to the

fascia below the ribs with three sutures of silk. Great improvement reported six months after the operations.

Case XXX. E. B., thirty-four, married three years; one child thirteen months old. Some leucorrhea; dysmenorrhea. Diagnosis: Retroflexion; uterus large; chronic endometritis; left ovary enlarged and prolapsed. Uterus steamed; retention cysts in the left ovary were punctured with the cautery; uterus suspended. Has been unwell once since getting home; flowed the usual time and amount; no pain: has no leucorrhea.

Case XXXI. C. N., twenty-nine, married four years; one child two years ago. Backache; sagging and dragging down; considerable leucorrhea. Diagnosis: Retroversion; chronic endometritis. Uterus steamed; retention cysts in left ovary punctured with cautery; uterus suspended. Been unwell once; flowed as usual; little pain; has a little leucorrhea.

Clinical Department.

MASSACHUSETTS GENERAL HOSPITAL. CLINICAL MEETING OF THE MEDICAL BOARD.

Regular meeting, December 15, 1899, Dr. C. B. Porter in the chair.

IDIOPATHIC DILATATION OF THE COLON.

Dr. R. H. Fitz showed a case of this affection in a child aged two years and one month. The patient had been nursed until twenty-three months old, and since the age of eleven months had also been fed. Constipation had existed from birth, intervals of several days being frequent, during which no dejections occurred, and then only from the use of laxatives or enemata. When six months old there were frequent loose discharges during a period of two months, and since then constipation had been more marked than before. There had been a considerable progressive and symmetrical enlargement of the abdomen, with slight temporary diminution in size, dependent upon evacuations of gas and feces. At present the distended abdomen is everywhere tympanitic, although the abdominal walls are sufficiently flaccid to permit the distended intestinal coils to be readily palpated. There is no obvious cause of obstruction to be determined, and the general nutrition of the child is unaffected. The case is regarded as one of infantile dilatation of the colon, due to obstinate constipation. As there are no urgent symptoms, and sufficient temporary relief is to be obtained by laxatives and enemata, it is considered inexpedient to recommend at present any so radical a measure as extirpation of the distended portion of the large intestine. The mother has been informed of the nature of the affection and of the importance of continued medical supervision of the child.

Dr. J. J. Putnam showed the following cases:

I. INSTRUCTION IN CO-ORDINATION IN TABES.

This was a patient with tabes, who, about a year and a half before, had became rapidly ataxic, so that, finally, he was almost wholly confined to his chair. The case was shown to illustrate the benefit which may be obtained from systematic instruction in co-ordination. The patient had been taught by Mr. Harding to stand and walk and to do various exercises, first with two chairs, then with crutches, then with canes, and finally alone. Considering the difficulties which had to be met, he had made good progress.

II. MUSCULAR DYSTROPHY.

This was a patient with advanced muscular atrophy of the dystrophic variety. The case was reported partly as an illustration of that type of disease, partly in order to show how long such patients may continue to live and even work, in contradistinction to the case of those with atrophy of spinal origin. This patient is now about thirty years old, and all the skeletal muscles are involved, and, in addition, the muscles of the face. The deltoids, the supra- and infra-scapular muscles and those of the forearms and hands and of the calves are much better preserved than the rest, and the first two groups mentioned are remarkably large, firm and dense. The disease began when the patient was thirteen years old and has been slowly progressing ever since, yet in spite of this fact, and even though there is double facial paralysis and the erect posture can only be maintained by skilfully balancing, he is still able to support himself, in a measure, by peddling.

Dr. G. L. Walton showed a

CASE OF ACROMEGALY.

Constant relation between this disease and lesion of the pituitary body has been disputed on the ground that such lesion has been found without sign of acromegaly, and conversely that post-mortem examination in acromegaly does not always show pituitary disease. In view, however, of the coincidence of these affections in the vast majority of cases, it is pertinent to inquire whether these apparent discrepancies may not be reconciled, a reconciliation towards which Dr. Brooks has made a decisive step in practically establishing the fact that acromegaly is due only to *increased secretion* of the pituitary gland. It follows that a destructive lesion of this gland will not produce acromegaly unless the secretion is increased; the cases of acromegaly not accompanied by post-mortem change in the pituitary body may be due to the fact that the increased secretion was not accompanied by obvious physical abnormality of the gland. In this connection I should like to exhibit a section, prepared by Dr. Mallory, from the pituitary tumor of our late colleague whose case was reported in the Journal of December 7, 1899. The specimen shows several large collections of colloid, showing the active secretion, and possibly increased secretion, of that part of the gland not destroyed by the sarcoma. In this case sarcoma was not only demonstrated by the post-mortem finding, but was indicated by the clinical history, the rapid course and early fatal termination offering a marked contrast to the history of uncomplicated acromegaly, the latter disease running a course of perhaps fifteen to twenty years, without metastasis, spinal headache or vomiting, a history pointing to hyperplasia of the gland rather than to malignant invasion.

Individuals presenting moderate variations from the average type in form or feature (variations suggestive of altered function of the pituitary gland either within or without the limits of health) are not infrequently observed, but the opportunity is rare to study a typical case of pure acromegaly. Such a type is presented by this patient, for whom we are indebted to Dr. Howard, under whose observation he came at Tewksbury.

The patient, a teamster, fifty-nine years of age,

height five feet, ten inches, has noticed progressive weakness, loss of virility, and pains in various parts of the body during the past fifteen years; during the same time the lower part of his face, and his hands and feet, have increased steadily in size. You will notice first the facial aspect: the face is very long, the lower jaw massive and projecting so that the lower teeth (formerly on a level with the upper) are now fully half an inch in advance, but without the separation of teeth usually found in these conditions. The head, while large (he wears a 7¾ hat), has not increased proportionately in size. The nose is large and broad, the ears long and wide, the tongue large in size. The hands are typical; you will note the general square appearance of the finger tips; the length of the hand (8¾ inches), the breadth (4¼ inches), and the thickness are unusual, these measurements being equal to the largest recorded in Dana's text-book. That the bones take part in the hyperplasia is shown by this skiagraph, in which you will also note the spongy texture and comparatively indistinct edges of the terminal phalanges. The chest measures 46½ inches; the feet are large and bulky, though the increase is not quite in proportion to that of the hands. The patient's lack of vigor is in marked contrast to his bulk.

Dr. E. W. Taylor demonstrated

A CASE OF POLIENCEPHALITIS SUPERIOR AND INFERIOR, WITH ACUTE ANTERIOR POLIOMYELITIS.

The patient, a previously well man of twenty-seven, without other venereal history than gonorrhea seven years ago, was confined to the bed for three weeks in January of this year with an attack supposed to have been influenza. On recovering from this acute — probably infectious — disorder the following conditions persisted, whether of sudden or relatively gradual onset is not known: Paralysis of both sixth nerves; of right seventh nerve; of right eighth nerve — much impaired hearing; paresis of motor portion of right fifth nerve and of the tenth and twelfth nerves. Associated with this involvement of cranial nerves was a flaccid, atrophic paresis of both arms, but particularly of the left. There has been considerable improvement since the onset of the disease, but the paralyses mentioned are still well marked. There are, at present, altered electrical reactions. [This case will be reported more completely later.]

A SECOND CASE OF CHRONIC CYANOSIS WITHOUT ASSIGNABLE CAUSE.

Dr. Richard C. Cabot showed the following case:

F. S., a spinster of forty-nine, a native of Roxbury, and a rubber-worker by trade, came to the Out-Patient Department, January 5, 1894, complaining of vertigo, weakness, a dry, bad-tasting mouth, and constipation. What was thought to be a blue line due to lead was noted on her gums. She was given cascara and potassic iodide, and did not appear again till a year later, January 12, 1895.

At this visit it was noted that the knee-jerks were normal and wrist-drop absent. The urine was pale, 1.011, with a trace of albumin, a few hyaline, granular and fibrinous casts, one having blood and fat adherent. Dr. Blood found "considerable lead in 1,040 cubic centimetres." Blood examination showed 120 per cent. of hemoglobin. January 22d she was admitted to the hospital under Dr. F. C. Shattuck, and the following history obtained: Family history good, except that her father died of "consumption of the blood." Otitis media at eighteen. Several attacks of what was apparently acute articular rheumatism; menopause in 1891; habits good. Since the menopause, has been troubled off and on with vertigo, palpitation and headache. Feels slightly dizzy most of the time and at intervals, from no apparent cause, the room begins to swim about, and she has to grasp at something for support. Attacks are ephemeral. No tinnitus, nausea or eye symptoms.

Palpitation and precordial distress, on excitement or exertion, for seven or eight years; slight dyspnea on exertion; no edema. Constipation, chronic.

Headache, frontal, more or less for years; worse for four months. Blueness of lips noticed by sister six months ago. Four months ago, after having three teeth drawn, got a bad stomatitis. Itching, occasionally troublesome at night, with burning sensation all over. Polyuria noticed for a year; has to pass urine two or three times at night. No hemorrhages.

Examination. — Face and mouth very markedly cyanotic; conjunctivæ much injected. *No* lead line. Heart negative, except a slight systolic murmur in the pulmonic region. Edge of liver palpable. Spleen considerably enlarged up and down (and up to sixth rib and two fingers below rib margin). No ascites. Gums bleed very easily. Hands and feet very blue; fingers not clubbed. *Tâche cérébrale* marked. Scratch marks on trunk. A patch of eczema in the left iliac region; lungs negative. Urine pale, 1.000; a slight trace of albumin and a few hyaline casts; a faint trace of bile was present. Hemoglobin, 120 per cent. Spectroscopic examination shows two bands of oxyhemoglobin and no others.

After a week's stay the liver had receded to the rib margin, but the spleen was still enlarged. The vertigo and cyanosis decreased considerably under quinine and potassic iodide, but the hemoglobin remained 120 per cent. After a stay of two months she was discharged March 28, 1895.

Four years later (April 4, 1899), she came again to the Out Patient Department with the same complaints and in the same condition. I saw her at this time, and counted over 12,000,000 red cells in a cubic centimetre of her blood. Her symptoms seemed to have continued unabated since her last appearance at the hospital, but the sponginess and bleeding of the gums were now the most troublesome thing. The attacks of vertigo come every two or four weeks and make her stagger as if drunk. Has lost twenty pounds in six years. The skin now showed considerable bronzing, especially about the axillæ, but small, leucodermatous patches are scattered over the trunk. Cyanosis is as marked as ever, especially on the mouth. The gums are spongy and sore. Retinal examination showed dark and dilated veins, while the arteries looked normal, or a trifle contracted (Dr. Amadon). The liver dulness began at the fifth rib, and the edge of the organ could be felt, three fingers' breadth below the costal margin. Spleen reaches a hand's breadth below the ribs. Urine, 1.012, albumin, .1 per cent; many hyaline and granular casts, some with blood and fat on them; few coarse granular casts; numerous abnormal blood globules. Blood: red cells, 9,252,000; white cells, 10,600; hemoglobin, 110 per cent.

Ten days after entrance venesection was done, and six ounces of blood withdrawn; patient felt relieved by it. Two hours after the bleeding a blood count showed: red cells, 10,032,000; white cells, 5,800; hemoglobin cells, 120 per cent. Differential count: polynuclears, 80.8 per cent.; lymphocytes, 15.2 per cent; eosinophiles, 3.2 per cent.; mast cells, .8 per cent. Five normoblasts were seen while counting 500 leucocytes. Three days after, eight ounces more blood were withdrawn. A blood count of a drop taken from the spurting stream showed 9,580,000 red cells.

A month later she was discharged in about the same condition as at entrance. During this day she had an attack of pain, tenderness, redness and swelling in the toes of the right foot; relieved by salicylates.

December 9, 1899, she re-entered for similar symptoms, and physical examination showed practically the same condition. Spleen extends to navel. Red corpuscles, 11,352,000; white corpuscles, 8,300; hemoglobin, 105 per cent. Differential count of 400 cells showed: polynuclears, 77.25; lymphocytes, 18.75, eosinophiles, 2.75; myelocytes, 1.25. While counting these, two normoblasts and two microblasts were seen. The red cells were of uniform and normal size and well stained. Pulsation was marked in many of the superficial veins, and the veins of the fundus oculi were four or five times their normal diameter. The gastric contents on two occasions showed the absence of free HCl.

The case is very similar to one which I reported in the *Boston Medical and Surgical Journal* in December, 1899. I do not believe that we are here dealing with a genuine plethora, but with a venous congestion, the cause of which, however, remains a mystery.

Dr. J. C. Warren reported the following cases:

I. RESECTION OF A PORTION OF THE LIVER FOR ADENOCARCINOMA OF THE CYSTIC DUCT.

Dr. Warren showed a specimen of adenocarcinoma of the cystic duct which was removed by operation on October 10, 1899. The patient, a woman of fifty-seven, had for three months noticed a tumor in the right hypochondrium, which had given rise to considerable pain. There were no other symptoms suggestive of its origin. Incision was made in the right semilunar line, and a distended gall-bladder found, from which were removed thirteen large gall-stones. The probe showed a stricture of the cystic duct, which was found on exploration to be caused by a tumor about the size of an olive, consisting of a dense white fibrous growth. A fragment of the growth removed was found by Dr. Whitney to be carcinoma. The edge of the liver was now seized with double hooks and drawn forward and upward over the cartilages of the ribs. A wedge-shaped portion of the liver, including the gall-bladder and cystic duct, was removed by the Paquelin cautery knife, with little or no hemorrhage. As the lobe of the liver was dropped back into the peritoneal cavity, the cut edges fell into apposition. A drainage tape was placed between them, the end being brought out of the wound, which was closed in the usual manner with silkworm-gut sutures.

Pathological report.— Gall-bladder and surrounding portion of the liver to the extent of seven centimetres was removed. Gall-bladder was dilated; measured 10 centimetres, and contained thirteen facetted calculi. The inner surface was slightly thinned. The cystic duct was surrounded for about two and one-half centimetres by a dense, fibrous growth, which microscopical examination showed to be adenocarcinoma.

The patient made a good recovery; wound healed well. Since leaving hospital, she has had no return of symptoms, but was unable to be present.

II. FRESH FRACTURED PATELLA, SUTURED WITH CATGUT THROUGH THE PERIOSTEUM.

Dr. Warren showed a patient who had entered the hospital less than seven weeks before with a fresh transverse fracture of the patella. He operated about an hour after the injury; made a curved incision below the patella, washed out the joint cavity with hot salt solution and sutured the capsule with chromicized catgut. The wound healed solidly by first intention, and in three weeks passive motion of joint and massage were begun. In six weeks the patient walked alone and without crutches, and was able to bend the knee to a right angle.

III. TWO CASES OF RUPTURE OF QUADRICEPS EXTENSOR TENDON.

Dr. Warren also mentioned two cases which he had operated recently for rupture of the quadriceps extensor tendon. In one case the operation was performed four days after the injury; in the other, six weeks after. In both, animal tendon was used as the suture material to hold together the divided ends. In both cases the capsule of the joint was found ruptured in the same way as is seen in fracture of the patella. The lacerations in the capsule were sutured with catgut; those in the tendon with four stout kangaroo-tendon sutures. In the case operated on six weeks after injury the rectus muscle had contracted about three fingers' breadth from the patella, and could only be brought down after several transverse incisions had been made in its substance. In the case operated upon four days after injury there was no retraction whatever of the muscles. Both cases made excellent recoveries, and in a few weeks the patients regained perfect function of the extensor muscles of the thigh.

Medical Progress.

REPORT ON PROGRESS IN THORACIC DISEASES.

BY GEORGE G. SEARS, M.D., AND JOHN W. BARTOL, M.D., BOSTON.

TRAUMATIC CHYLOTHORAX.

Hahn[1] reports a case of traumatic chylothorax, which from his account appears to be the ninth recorded case of this affection following accident. As other possible causes he details carcinoma, tuberculosis, syphilis, filaria sanguinis and thrombosis of the left subclavian vein. The protected situation of the thoracic duct is described and the conclusion reached that injury to it can be done only by fracture of a vertebra or serious crushing of the surrounding tissues; in order for chylothorax to result it is also necessary for the costal pleura to be so injured as to allow passage of the chyle into pleural cavity.

[1] Deut. med. Woch., No. 25.

In his patient, a man run over by a wagon, there was, on first examination, fracture of two ribs on the left, evidences of injury to spine and dulness from the fourth rib downward on right. On the eleventh day this dulness suddenly increased, with marked dyspnea, which grew so rapidly worse that three days later the chest was tapped and 2,000 c. c. rose-colored opaque fluid drawn off. Tappings then became necessary for relief of symptoms every few days, averaging 3,000 c. c. of fluid, which after third tapping lost its reddish color (due to blood) and was milky white, presenting physical and chemical characteristics of chyle. In all, during twenty-six days, there were drawn off 29,650 c. c. and at autopsy the pleural cavity contained 7,000 c. c.

Of the nine reported cases, four died and five got well, and the conclusion is drawn from study of the cases that in those recovering the main duct was not ruptured, but some of its branches.

TUBERCULOUS PNEUMOTHORAX.

Drasche,[2] in a forty years' hospital service, has had under treatment 10,212 cases of phthsis, 6,686 males, 3,526 females; of this total there have been 198 cases of pneumothorax, 158 males, 40 females. A large proportion of the cases were in twentieth to thirtieth years of life; in 55 per cent. it was right-sided, in 44 per cent. left-sided, and in three cases bilateral. As immediate causes for the development of pneumothorax are to be reckoned violent coughing or any exertion which brings such a strain to bear upon the lung as can effect rupture of an existing cavity: thus many patients have been made perfectly conscious of the rupture by a sharp pain immediately after coughing, vomiting, defecation or lifting. As might be expected from the usual location of tuberculous process, a large proportion of the ruptures (71 per cent.) occur in the upper lobes.

In most cases the perforation is single and small (pin-head to hazel nut); when there is a pyopneumothorax the effect of the pus is to increase the destruction of lung tissue; an effusion may remain serous for months or become purulent within twenty-four hours of the rupture. Spontaneous closure of the perforation, when it takes place, does so probably by the spread of a pleuritic membrane.

Pneumothorax is one of the most serious complications of phthisis but is not necessarily fatal in itself, as is shown by evidences of perfectly healed lesions found post mortem, and also by those cases which have healed spontaneously under observation or as result of operation; still the treatment of it has remained, even in hospitals, mainly expectant, and attempts to promote healing by operative interference are prevented by prognostic pessimism.

It should not, however, be accepted as a fact that perforation necessarily means one further step in a fatal disease, but it should be borne in mind that phthisis, even of advanced degree, is capable of being arrested. Up to within a short time, practically the only indication for operative interference has been compression of the lungs and heart threatening suffocation, but at present there is a tendency to operate with the hope of promoting healing, a hope which is justified by statistics. Of the 198 cases, 158 were treated expectantly and 30 by operative interference; of the former, 5.5 per cent, and of the latter, 13.5 per cent., were discharged living; of the unoperated cases there were living up to six weeks and over, 13.2 per cent., of the operated, 37.9 per cent. Operation is always indicated in cases of threatening increase of dyspnea, cardiac oppression and thoracic tension. For puncture a medium-sized trocar should be used; with recurrence of symptoms puncture may be repeated or permanent drainage established. Pyopneumothorax is not necessarily a contraindication to operation. Many such cases are much improved subjectively and prolongation of life secured.

[2] Wien. klin. Woch, Nos. 45, 46 and 51.

POSSIBLE DANGERS OF THORACENTESIS.

The fact that evacuation of pleuritic effusion is often followed by rapid spread of tuberculous changes in the lung is emphasized by Pinquet.[3] The theory that a large number of all serous pleural effusions are tuberculous in origin is sustained, and, on account of the uncertainty as to serious results of tapping any given case, stress is laid on the advisability of avoiding interference if possible; and when the patient's comfort demands relief drawing off as little as possible; the theory being that the effusion keeps apart and at rest the two pleural surfaces loaded with tubercle bacilli, thus preventing further irritation and spread of the invasion.

Mollard, under whose direction the work was done, thinks the danger of permanent collapse of lung and pleural adhesion, as a result of non-interference, has been overestimated.

THE TREATMENT OF PNEUMOCOCCUS EMPYEMA.

O. Vierordt[4] speaks of the impression more or less prevalent in the profession that empyema from infection with the pneumococcus runs a more benign course than that due to other micro-organisms, and compares it with his own experience, which was almost exclusively confined to children. In 1897 he met with 16 cases of the disease, of whom five were surely due to the pneumococcus. Three of these died from extraordinarily severe complications. The following year he also treated 16 cases, with two deaths. Ten were due to the pneumococcus and one died. In other cases, a report of which is incorporated in the paper, an empyema so small as to be difficult of diagnosis reduced the patient to a critical condition, which improved after the evacuation of at times a few cubic centimetres of pus. These observations, he says, show exclusively the extreme variations in the malignity of the affection, which is little, if at all, dependent on the amount of pus. They further show how much risk one may run, in spite of their undoubtedly frequently benign character, and irrespective of the amount of the exudate, in delaying operation. At least so far as children are concerned, and probably also for older persons, there is no difference, from the standpoint of treatment, between the metapneumonic and other forms of empyema. A prompt and complete evacuation is necessary.

A RARE CASE OF INTERNAL THORACIC INJURY.

Kolbe[5] prefaces his account by the remark that it is certainly a rare occurrence for a single fall on level ground to produce in a healthy child a wound within the thoracic cavity that forthwith results in pneumothorax and a quickly spreading cutaneous emphysema

[3] Thèse de Lyon, 1899.
[4] Deut. Arch. f. klin. Med., 1899, Bd. lxiv.
[5] Deut. med. Woch., August 24, 1899.

of neck, face, chest, upper arm, back and abdomen. The patient, a seven-year-old girl, was pushed down by a companion, but was able to get up and walk home, when she complained of pain in her chest and was put to bed; during night the pain increased and a cough developed, with blood-stained expectoration. On the third day with a continuance of these symptoms there was noticed an increasing swelling in the right neck and upper right chest. Kolbe saw her first on the sixth day. He found a right-sided pneumothorax and a very extensive cutaneous emphysema extending on right side from cheek to mid-scapula behind, and five cm. below costal margin in front; there was marked dyspnea; temperature slightly elevated; no fractures or dislocations.

The emphysema, favored by paroxysmal attacks of coughing, steadily increased and the effect of a firm bandage over absorbent cotton applied to thorax was to increase it in uncovered portions, so that both eyes were closed and the face swollen out of all recognition. Slight improvement in the condition began five days after application of the dressing and it was re-applied in greater extent. Within a few hours of the re-application there ensued a very violent paroxysmal attack of coughing lasting half an hour and ending with the expectoration of a cherry stone embedded in a coagulum of blood and mucus; from this time on, rapid improvement and complete recovery in nine days. It then was discovered that she had been eating cherries at the time of the accident and the sequence of events is explained on the theory that with sudden inspiration the stone was carried to a branch of the right primary bronchus, became imbedded and held fast by a reflex spasm, and formed so complete an obstacle to the egress of air that a sudden blow over the portion of the distended lung that could not empty itself caused a rupture of lung tissue and also of the two pleural layers.

STAB WOUND FOLLOWED BY PNEUMOHEMOTHORAX AND PNEUMOHEMOPERICARDIUM.

Baracz[6] reports such a case, which ended in complete recovery. The wound, received in a duel, began at left border of sternum in fourth intercostal space and extended obliquely outwards four cm. ending just under nipple; by retracting its edges a wound in pleura one cm. long could be seen through which the air swished with each inspiration. The outer wound was closed and there was no interruption in its healing. Examination showed dulness and diminished respiratory murmur at base of left lung. Signs of fluid and air in pericardium were first positive on fifth day, when patient complained of a swishing sensation in cardiac region and there was audible at a distance of one-half to one meter, synchronous with systole, the characteristic sign first described by Morel-Lavalle as the water-wheel murmur. This lasted only one day, but there was later demonstrated a definite enlargement of cardiac flatness. On the eleventh day there was evidence of effusion on the right side, and on the seventh a very marked increase in the fluid in the left chest, which on exploratory puncture proved to be blood. Baracz concludes that this sudden increase was due to a secondary hemorrhage resulting from absorption of clot and increased activity of heart. In eight weeks patient was entirely well.

[6] Wien. klin. Woch., No. 47.

THE NIGHT AIR OF NEW ENGLAND IN THE TREATMENT OF CONSUMPTION.

Millet's[7] paper deserves more than a passing notice. He has cut loose from all traditions as to the awful dangers of draughts and night air in consumption, and furthermore has had the courage to act on his convictions. He reports five cases in which the essential part of treatment consisted in the patients spending the night in the open air, the beds being placed on an upper piazza or on a platform built over an L or a bay-window in their own homes in a New England shoe town. "Dampness and draughts are bugbears, and need not be considered for a moment. Many times these patients have found their bed coverings and night clothes wet with dew, and once in a while a summer rain has disturbed their healthful slumbers, but with no harm." During the day, the patients, if strong enough, followed their regular vocations, for example, working in a shoe shop; when not at work they have spent most of the time out of doors. Cough mixtures and sedatives were not given, almost the only medicines used being nux vomica and an occasional laxative. It was found that the more air the more appetite and less cough. All five cases showed remarkable improvement.

PROBLEMS IN TUBERCULOSIS STILL UNSOLVED.

No one interested in the subject should miss a paper by Trudeau,[8] which, although going beyond the limit of application to thoracic disease, still has so much of general interest that it is summarized here. The significance of virulence is alluded to; does it mean increased capacity for producing toxic effects, or simply increased capacity for rapid growth? Adenoid growths in nasopharynx are probably much more frequently the channel of access than is generally supposed. How may the problem of individual and racial immunity and insusceptibility be helped by a study of the discoveries: (1) that the resistance of chickens to the human bacillus can be overcome by using for inoculation bacilli that have been previously cultivated in celloidin capsules, inserted and kept for some time within the peritoneal cavity of these birds, — this method allowing access of the body fluid to the bacilli and the escape of toxins into the circulation, while preventing egress of the bacilli, — and (2) that the resistance of guinea-pigs to avian bacilli yields, when these bacilli have been passed through a series of rabbits, animals which are susceptible to the avian variety. Does the tuberculous individual, like the syphilitic, acquire an immunity during the progress of the disease? Prophylaxis must be carried along the lines of establishment of sanitaria and the education of the masses as to the sources of danger and methods of prevention. But it is in the details of these very matters that we are in need of further investigation.

As aids to clearing up obscure diagnosis, the x-ray and tuberculin test are destined to gain in value by being more frequently used. The mechanism of the tuberculin reaction needs further investigation as to the best method of applying it, its exact value, its discrepancies and its possible dangers. The latter have probably been over-estimated, and while it is apparently true that the "reaction" is caused by an intense hyperemia set up in the various tuberculous foci, and

[7] Maryland Medical Journal, January, 1900.
[8] Johns Hopkins Hospital Bulletin, July, 1899.

a liberation therefrom of the toxins which cause the characteristic symptoms of the reaction, there is no proof at present that the disease is spread, or new foci established. The stronghold of treatment will continue for the present, at least, to be in climatic and open-air measures, and further investigations as to methods and modification will be of much value.

Little of practical avail has yet been accomplished in the attempts to produce immunity or cure by inoculation; the outlook, however, in spite of certain inherent difficulties, is not hopeless. Just now the most promising line of research seems to be the possibility of establishing immunity by inoculation with living cultures of attenuated bacilli.

(To be continued.)

Reports of Societies.

SUFFOLK DISTRICT MEDICAL SOCIETY. SECTION FOR OBSTETRICS AND DISEASES OF WOMEN.

C. H. HARE, M.D., SECRETARY.

Regular meeting Wednesday, November 22, 1899, Dr. R. A. Kingman in the chair.

Dr. Frederick W. Johnson read a paper entitled

STEAM IN THE TREATMENT OF CHRONIC, HYPERPLASTIC AND SENILE ENDOMETRITIS, PUTRID ABORTION AND PUERPERAL SEPSIS.[1]

Dr. Burrage: I have not had personal experience with the method, but should like to say a word with reference to it. I have seen it used by Dr. Johnson, and it seems to me it is a most valuable addition to our therapeutic resources. It is, however, one that I somewhat fear, for I have felt that it is hard to control; that is, I think that Dr. Johnson has pointed out that if a short application is to be made that the temperature of the steam must be kept near the maximum, 212°, and if a long application, the steam may be partly condensed, but even then, it seems to me, that theoretically, and I must speak of it on theoretical grounds entirely, it is difficult to control the temperature, and to limit the cauterizing effect in any given case. Of course it is no argument against steam to say that it will obliterate the uterine cavity; we know that excessive curettings will do practically the same thing. I saw a patient to-day whose uterine cavity is not entirely obliterated, but partially so, as a result of a curetting done eighteen months ago by a friend of mine in a neighboring town, and she has had amenorrhea virtually ever since. It seems to me there is a very distinct danger from the steam, and that is in the septic cases if there happens to be a perforation of the uterus. Of course, in cases of criminal abortion there may be a perforation, and there may be in cases that have been curetted. We all know how soft the uterine tissue is in septic cases, and how easy it is for a curette to slip through. There was a fatal case recently reported in one of the New York journals where the steam got into the peritoneal cavity through a perforation in the uterus and the patient died.

Then, again, in certain cases, where there is very abundant tissue in the uterus, it seems to me that steam ought to be used as a supplementary measure rather than the chief measure. I curetted a case last Friday where the uterus was large, and there was much tissue in the cavity, some of the pieces as large as my little finger, and I fail to see how it would be possible to destroy all that tissue with steam without destroying the uterine wall in places where the tissue did not occur, near the cervix for instance, and if the tissue were destroyed, it seems to me not a surgical procedure to destroy it and leave it to come away slowly. To my thinking, in those cases the steam does not take the place of the curette or curette forceps or some similar instrument for removing tissue directly. As a supplementary measure, it seems to me it has great advantage. In senile endometritis it is a very good measure, and wherever we want to obliterate the uterine cavity, but the matter of the lack of control is, in my mind, a very strong argument against its use, and I cannot believe that it is going to take the place entirely of the curette. I think that careful curetting, using in addition to the sharp curette with flexible shank, a very small Simon curette to go into the horns, is the most rational method of treating cases of endometritis, and then following the curetting, as I do still, although it sounds old-fashioned, by swabbing with pure carbolic acid. Pure carbolic is an antiseptic, and it will go into the nooks and corners of the uterus and cauterize any islands of tissue that may be left. I do not feel there is the same danger of a small amount of fluid going through a patulous tube or a perforation, though I do not use carbolic when perforation is suspected, as there is danger of a vapor going through. Steam is a valuable agent in the cases that have not been relieved by curetting. We see patients who have had several curettings and have not been relieved, and I think these would be good cases for steam, and in senile endometritis, and in certain septic cases, it seems to me, it would be of great advantage, but I should hesitate to use it in all cases instead of the curette. I think curetting properly done is a wiser and much better method.

Dr. Johnson: I should like to say in reference to the temperature of the steam that it cannot be any hotter than 212° anyway, and by repeated experiments with a thermometer inside the uterus while I was steaming the temperature depended entirely upon the amount of moisture inside the uterus. If the uterus was dry you could get 212° easily. With the apparatus I described you get almost no pressure. Now, in reference to the death Dr. Burrage spoke of, if he will look up that article again he will see that the steaming was done with the Russian apparatus, by which you can get enormous pressure, and I should think with an apparatus of that kind you might do at times a good deal of harm. In saying that the temperature was sometimes 104° to 110° C., I was quoting. I do not advocate that. I advocate the use of the steam as it comes out of an ordinary throat atomizer, and practically there is no pressure at all, only what you get from its being put through the small tube that goes into the uterus. Neither did I write the paper with the idea that steam was to take the place of the curette in every particular. I used steam after reading articles of prominent men who had used it extensively, to see what it could do.

In organizing, the Watertown, Mass., Board of Health has chosen Dr. B. F. Davenport as chairman.

Recent Literature.

The Mechanics of Surgery. By CHARLES TRUAX. Pp. 1,024, with 2,381 illustrations. Chicago. 1899.

The character and purposes of this somewhat unique book are perhaps best described by quotations from the author's preface, which states that its aim is to illustrate and describe such mechanical appliances as research and experience have proved to be suitable, or best adapted to the purposes for which they are designed; to furnish information relating to surgical instruments and appliances which is not only from the point of the maker but also from that of the user of such apparatus. Extensive experience in both fields has apparently fitted the author to fulfil this task. It is intended to furnish the doctor with information which will enable him to select and order any instrument or appliance, be it a scalpel, stethoscope, electric battery, or an artificial leg, without depending upon a surgical-instrument catalogue or dealer, the former giving, as a rule, no other information than the name and price, the latter often buying and selling the goods as a hardware dealer does common tools. It also tells what is commonly required for any particular operation or ordinary clinical investigation. No attempt has been made to include all instruments, but only those in general use which are accepted as the standard patterns, or recommended by good authority. The introductory chapter contains a few facts relating to the history of surgical instruments. Then follow some details of construction and care of instruments. Next the subject of mechanical aids in clinical diagnosis, for example, microscopy, urinary analysis, blood examination, etc. The next chapters are devoted to hospital equipment, including sterilization, anesthesia, and other subjects. Following are the instruments, appliances and dressings necessary in general work in minor and major surgery. These are fully tabulated and described. Regional and special surgery is assigned to its specific chapters. Two lists are furnished, one intended for hospital work, the other as a guide to operative work in private practice. The writer has tried to make these lists complete to the last pin and bandage. The concluding chapter, on prosthetic surgery, is devoted to a subject usually neglected, and on which the author has spent considerable thought and time in collecting data. The chapter on orthopedic appliances is more satisfactory than is usual with such descriptions.

The book is profusely illustrated, well arranged, and contains much information which will be for the benefit and profit of its readers. Many ways are readily suggested in which its data can be utilized. Its chapters treat of subjects, a knowledge of which is usually acquired only by years of personal experience and extended observation.

An American Text-Book of Surgery for Practitioners and Students. Edited by WILLIAM W. KEEN, M.D., LL.D., and J. WILLIAM WHITE, M.D., Ph.D. Third edition, thoroughly revised and enlarged. Pp. 1,228. Philadelphia: W. B. Saunders. 1899.

This book is well known to the medical public. The authors state that nearly 29,000 copies have been sold, and that it is used as a text-book in more than one hundred medical colleges. It has been revised to keep the book fully up to date. In regard to the general character and appearance it is hardly necessary to speak in detail. It resembles its predecessors. Among the new features are the subjects of serum therapy, leucocytosis, the Kralein system of cerebral localization, the congenital hip operations of Haffa and Lorenz, the Allis method of reduction of hip dislocations, lumbar paracentesis, the French method of forcible correction of Pott's deformities, some additions to gastric surgery, the surgery of typhoid fever, skiagraphy, advances in surgery, the surgery of the ureter, and some of the more recent changes in antiseptic technique. The sections on appendicitis, fractures and gynecological operations have been revised and enlarged. The chapters describing the surgery of the eye and ear have been omitted in this edition.

The book as it now appears fully attains the high standard of the earlier editions. The subject of surgery seems to be very well covered, at least as thoroughly as is possible to do in a work of this character. The authors who, in addition to its editors, have contributed to the volume are Drs. P. S. Conner, F. S. Dennis, C. B. Nancrede, R. Park, L. S. Pilcher, N. Senn, F. J. Shepherd, L. A. Stimpson, and J. C. Warren, a list which surely ought to attract attention to and arouse interest in the book. In reviewing it one thought was suggested several times before the task was completed. It was that perhaps for the average reader at the end of a day's work the book would be more restful and convenient if published in two volumes.

Imperative Surgery for the General Practitioner, the Specialist, and the Recent Graduate. By HOWARD LILIENTHAL, M.D. Illustrated. New York: The Macmillan Co. London: Macmillan & Co., Ltd. 1900.

This book was written for "the practitioner of general medicine, who rarely takes up the scalpel, the specialist, whose path seldom leads him to the operating-room, and the recent graduate, who though versed in the lore of books and lectures, has seen but little surgery at close range." It deals only with diagnosis and the treatment of conditions necessitating immediate operative measures. It presupposes the absence of a surgeon, and the impossibility or inexpediency of moving the patient, or waiting for expert assistance. For purposes of clearness and directness, the author claims to have described only one good method of relief in each case.

The book is well published, with unusually large, clear type, and is beautifully illustrated. It reminds one of that attractive volume, the "Aseptic and Antiseptic Surgery" of Gerster. The text is systematically arranged and indexed. The story is interestingly, at times graphically, told. It is attractive from the implied success of each procedure and its freedom from doubt and uncertainty. Many valuable suggestions and expedients for use in emergencies are introduced. Minuteness of descriptive detail in many instances is noteworthy. In regard to some of the operative procedures recommended, it might be a matter of opinion as to the one best adapted for an emergency operation to be performed by one unaccustomed to surgical work. However, the book seems to fulfil very well the object of its author. He is to be congratulated on the success of his efforts and his contribution to medical literature. The book shows en-

thusiasm and interest, much time and thought, and a desire to produce the best. The text covers 412 pages, and contains 153 illustrations.

Collins and Rockwell's Physiology. A Pocket Text-Book of Physiology. By H. D. COLLINS, M.D., Assistant Demonstrator of Anatomy, and W. H. ROCKWELL, Jr., A.B., M.D., Assistant Demonstrator of Anatomy, College of Physicians and Surgeons, New York. Pp. 316. Philadelphia: Lea Brothers & Co. 1899.

As you read this book you will agree with the authors' statement in the preface, when they remark that they make no claim to original research. When you have finished the volume you will be inclined to add that they should have included in this remark originality of any description. In short, everything is culled from the various well-known text-books and simply boiled down, not to such an extent as a "quiz compend" perhaps, but still enough to establish a distant relationship to these doubtful blessings.

The book to a medical student is not very valuable, but it ought to make a very good high-school class book. Unfortunately (?) it does not contain any garbled facts about the poisonous and atrocious effects of alcohol and tobacco. Consequently it is a pernicious (?) book and is debarred from being adopted as a school book. If "brevity is the soul of wit," then the book scintillates with witty remarks. We do know that the mechanism of rhythmical contraction is contained within the heart itself. This joke explains the cause of the heart beat! Internal secretion, ductless glands, and the phenomena of inhibition are short comedies.

In favor of this book it may be said that it contains no *bad* physiology or antiquated hypotheses. It is nicely bound, well illustrated with clean cuts, and is printed on good paper.

Notes on the Modern Treatment of Fractures. By JOHN B. ROBERTS, A.M., M.D., Professor of Surgery in the Philadelphia Polyclinic. Pp. 162, with 39 illustrations. New York: D. Appleton & Co. 1899.

This interesting and suggestive little work contains the result of the investigations and study of the author of several subjects connected with fractures which have especially attracted his attention. The text of these brochures has been revised to correspond with Dr. Roberts's present ideas. The subjects discussed are all of importance and interest, particularly to those actively engaged in treating such lesions. They represent the complications rather than the routine work; for example, the question of an exploratory incision in the treatment of "closed" fractures and dislocations; subcutaneous nailing in fractures, with unusual tendency to displacement; fractures on the lower end of the radius, with forward displacements, etc. The book will repay a careful perusal. It contains several instructive illustrations.

Essentials of Physical Diagnosis of the Thorax. By ARTHUR M. CORWIN, A.M., M.D. Third edition, revised and enlarged. Philadelphia: W. B. Saunders. 1899.

This is the third edition of Dr. Corwin's little book. Although somewhat enlarged, it is still open to the same criticism which has been made on former editions, that in the effort to epitomize and condense, the essentials and non-essentials have received the same amount of emphasis. There is no perspective presented to the student. He meets a mass of facts which seem of equal value and have no apparent connection and which he must learn by an effort of memory and not through being taught the logical dependence of the signs on the conditions which cause them. The essential facts are all given, and in the hands of a competent teacher the book would be useful.

Surgical Nursing. By ANNA M. FULLERTON, Clinical Professor of Gynecology in the Woman's Medical College of Pennsylvania, etc. Third edition, revised and enlarged. Pp. 294, with 69 illustrations. Philadelphia: P. Blakiston's Son & Co. 1899.

This little book is one of the best of its kind. It is attractively and well written. The style is concise. It is well arranged. The data relating to aseptic and antiseptic technique incorporated in its pages are accurate. It treats more especially of nursing in abdominal surgery and in gynecological practice, but the principles of aseptic surgery in general are well presented with the most essential details. If the nurse does her work as directed in this book, it will be well done. The present edition fully equals in excellence its predecessors.

A Text-Book of Diseases of Women. By CHARLES B. PENROSE, M.D., PH.D., Professor of Gynecology in the University of Pennsylvania; Surgeon to the Gynecean Hospital, Philadelphia. Third edition, revised. Philadelphia: W. B. Saunders. 1900.

This third edition follows so closely upon the heels of the second that but little change has been necessary. The book is, as has been said before in these pages, essentially a text-book for students. It is clear, concise and thorough, and considered as a text-book for students, it is perhaps the best exponent of the modern school of operative gynecology which we have.

Golden Rules of Physiology. By T. WALKER HALL, M.B., Ch. B. (Vict.), and J. ACKWORTH MENZIES, M.D., C.M. (Edin.). Golden Rules Series, No. VI. London: Simpkin, Marshall, Hamilton, Kent & Co., Ltd. 1900.

Nothing new, nothing original, except the size, which is, roughly speaking, 7 x 10 x .5 centimetres, and into this small space is crammed a lot of useful physiological hints. The book was written chiefly for unfortunates "on the threshold of examination." As a simple "refresher" for the memory it may be of some use; otherwise it has no value whatever.

A Pocket Medical Dictionary. Giving the pronunciation and definition of the principal words used in medicine and the collateral sciences, etc. By GEORGE M. GOULD, A.M., M.D., author of the Illustrated Medical Dictionary, etc. Fourth edition, revised and enlarged; 30,000 words. Philadelphia: P. Blakiston's Son & Co. 1900.

Dr. Gould's dictionaries are deservedly popular. The total circulation, as stated in the preface to this fourth edition of the Pocket Dictionary, has now passed 100,000 copies. The small volume before us is compact and attractively bound with flexible covers. It should continue to fill a place in this its somewhat enlarged and elaborated form.

THE BOSTON

Medical and Surgical Journal.

THURSDAY, MARCH 15, 1900.

A Journal of Medicine, Surgery and Allied Sciences, published at Boston, weekly, by the undersigned.

SUBSCRIPTION TERMS: *$5.00 per year, in advance, postage paid, for the United States, Canada and Mexico; $6.56 per year for all foreign countries belonging to the Postal Union.*

All communications for the Editor, and all books for review, should be addressed to the Editor of the Boston Medical and Surgical Journal, 283 Washington Street, Boston.

All letters containing business communications, or referring to the publication, subscription or advertising department of this Journal should be addressed to the undersigned.

Remittances should be made by money-order, draft or registered letter, payable to

DAMRELL & UPHAM,
283 WASHINGTON STREET, BOSTON, MASS.

PROGRESS IN MEDICAL TEACHING.

A MEDICAL meeting of much more than usual interest and significance, to be published in full later, was held last week under the auspices of the Boston Society for Medical Improvement, on the general subject of "Medical Teaching." That a very active movement toward the improvement of teaching in medicine has developed within the last few years has been sufficiently evident to those who have followed the course of events, and it appears equally evident that positive results are to follow the introduction of the new methods. It was the purpose of this meeting to outline the changes which have been suggested, and to excite discussion as to their merits or shortcomings. In both of these objects the meeting proved a decided success, as shown by the perfectly clear presentation of the subject matter, and the extended discussion by many men more or less personally interested in the development of medical education.

As not infrequently happens, however, it was apparent that the exact meaning and scope of the proposed changes was not clear to the minds of all present, and that a certain confusion existed as to the various methods of teaching which formed the basis of discussion. There was a tendency to regard methods as antagonistic, rather than supplementary and directed to precisely the same end by somewhat different means. Nothing could be more unfortunate for reform than this setting up of two systems of teaching as rival claimants, one of which must succumb if the other be adopted. As a matter of fact, the adoption of one should mean the acceptance of the other if either is properly understood.

Three general changes in method were suggested at the meeting, and presented briefly by Dr. W. T. Councilman, Dr. H. L. Burrell, Dr. A. H. Wentworth and Mr. W. B. Cannon. The speakers were entirely in agreement in maintaining that the teaching of the future must be directed toward the intellectual development of the individual student, that the student must do his own thinking and draw his own conclusions, and that the instructor must act rather as a court of last appeal than as a painstaking director of the student's mental processes. For these reasons the extreme use to which the so-called didactic lecture has been put was discouraged as directly leading to intellectual dependence. About this there can be no confusion. The didactic lecture, as a means of medical instruction, must resign its place of pre-eminence, and assume, as we have frequently insisted, a position of less prominence, but of greater dignity, because more in keeping with the sort of instruction it is designed to supply. Our correspondent on another page is inclined to defend the old régime on somewhat sentimental grounds, but this is not argument, and some of us may even be inclined to think that we learned in spite of, and not because of, those same didactic lectures. In any case, whether the old method was bad or good, we are certainly not disloyal to our former teachers in demanding better things for the future. We can hardly progress by looking backward.

Admitting the desirability of the inductive method, how is it practically to be attained? This is the question which the various speakers set themselves to answer. Dr. Councilman spoke on the course in pathology at the Harvard Medical School, as carried out under the new plan of concentration. We have already commented in considerable detail on the theory of this system of teaching, and Dr. Councilman's remarks on the practical working of the plan showed, in the course in pathology at least, that the hopes of its projectors have been amply borne out. The students were made self-reliant, developed a highly gratifying enthusiasm, and passed a good examination. The lecture was in general subordinated to more direct means of instruction.

Dr. A. H. Wentworth spoke on section teaching, a résumé of his recently published paper in this JOURNAL for February 15, 1900. There was a very apparent tendency on the part of some of those who discussed this paper to misinterpret its significance and to question its originality. As we understand Dr. Wentworth's position, he claims no originality for the method, which, of course, has always been used wherever medicine has been taught. His contention simply is that it is the best method of teaching clinical medicine, and that it is possible to apply it to large classes. The application of a method recognized as valuable is Dr. Wentworth's service. He has demonstrated that it may be applied, not only to classes of ten or twenty, but to classes of a hundred or more, in such a way that each student may examine in the course of a year a large number of actual cases. He has worked out a plan for the Harvard Medical School which, in principle, may be used at other institutions. This, so far as we are aware, has not been attained before in anything like the completeness that Dr. Wentworth's plan of rotation renders possible.

Mr. Cannon's contribution to medical teaching, as many of our readers know, consists in the application to medicine of the "case system," which for many years has been used with success in the teaching of law. A detailed account of this method, which certainly demands attention, will be found in Mr. Cannon's original paper, published in our issue of January 11, 1900. The disputants at the meeting in question were again rather vague in the discussion of this communication, and were apparently not clear as to the exact meaning or the exact position in the curriculum of this "case method." In the first place, Mr. Cannon also claims no other originality than one of application. His plan provides a method of studying medi cine systematically and in a natural way by the use of case histories. There is no conflict with the system of "section teaching," as was implied in the discussion; it is designed rather to fill out the inevitable gaps left by any method of instruction which looks to patients alone for the material of study. It is therefore supplementary rather than antagonistic to the section teaching plan, and as such has a place of the greatest significance in the general scheme of teaching, as experience has already shown. The "young gentleman from the Medical School," as our correspondent terms Mr. Cannon, has himself had a large experience in teaching, and is, no doubt, quite aware of the fact that his ideas are not revolutionary, and that there is still some good in old methods. His contribution, properly understood, remains one of the most significant and fruitful that has ever been presented to a body of medical teachers.

The general ferment now going on is sure to result in marked improvements; of that the most conservative of us can have no doubt. We suspect the final outcome will be a system of teaching in which the didactic lecture will still be permitted to hold its head erect, and also one in which the principles of all the new ideas will find a definite abiding place, modified only to meet the requirements of advancing knowledge. Because we have learned in the past, is surely no reason why our successors should be forced into the paths we have laboriously travelled, if better ones may be found.

CHRISTIAN SCIENCE A MENACE TO THE PUBLIC WEAL.

It was stated last week that a child had died at Somerville under the treatment of a Christian Scientist, who gave the cause of death as pneumonia; that the Board of Health refused a burial certificate without a proper death certificate from an accredited physician, as required by law; that after much controversy a physician was allowed to view the body and burial was permitted. It now appears that the City Physician of Somerville was ultimately allowed by the friends to see the body, after several refusals; that he gave a death certificate, cause of death unknown, and secured a culture for bacteriological examination; that it is now shown that the child died of diphtheria and not of pneumonia.

It is time it should be made plain whence comes the validity of a death certificate, and what is required for the issuance of a burial permit. The State and individual communities, for the protection of their citizens, require certain duties of physicians; these duties are in the nature of police service. Among them are the reporting of contagious diseases to boards of health, the signing of death certificates, and the granting by boards of health of burial permits. The essential importance of the correct discharge of these duties for the prevention of the spread of disease, for the saving of life, for the control of crime, for the approximately proper preparation of vital statistics, is so evident that it seems hardly necessary to dwell upon them. And they are essentially important not to the physician as a professional man, but to the people at large. It is the people and not the physician who will suffer if these duties are overlooked or ignorantly and carelessly attended to.

We have no intention of discussing the question whether Christian Scientists should be allowed to suffer and die unnecessarily if they so prefer, or even to help their relatives and friends to do so, but how far they are to be allowed to endanger the community at large.

What may be expected from them is shown in this Somerville case, as in others previously on record. It is shown again most clearly in the testimony before the Committee on Hygiene of the Maryland Assembly, printed on another page of this issue.

THE QUESTION OF PRIZES.

It is a matter worthy of note that the Samuel D. Gross prize of $1,000 has not been awarded this year, owing to the fact that no essay submitted was considered sufficiently meritorious. This is a fate which we continually see overtaking prizes of less value from which we are led to the belief that the standard set for work worthy of consideration is very high. No doubt this is, in a measure, the case, which is after all merely a confession that really able men are not apt to compete. As we have recently taken occasion to point out, prizes are yearly increasing in number and decreasing in value, until they have come to lose a great part of their interest. When, however, a prize which in addition to what honor it may bring also offers the successful writer $1,000, and stills finds no one of sufficient ability to present an essay, on a subject, too, in which thousands of men are interested, it would seem that but one conclusion is open to us, namely, that such a method of stimulating research is wrong in theory and unsuccessful in practice. It is to be hoped that in the future men with money to expend will perpetuate their names in some other way than through the establishment of prize funds, of which we have already enough and to spare.

MEDICAL NOTES.

THE PLAGUE SITUATION. — During the last week of February, there were 411 deaths from plague in Calcutta. The viceroy, Lord Curzon, addressing some of the plague-stricken patients, said he considered it his duty to visit all the quarters of the vast dependency committed to his charge. In spite of the fact that several new cases have occurred in Honolulu, the situation is very decidedly improved. At Hilo no new cases have been found and none are expected to occur. A suspicious case recently discovered in San Francisco has proved to be genuine plague.

DEATHS FROM TUBERCULOSIS IN DENVER, COL. — Tuberculosis is reported to have caused more deaths in Denver, Col., during 1899 than any other disease. The annual report of the Health Department shows that the tuberculosis mortality was 536 for the year ending December 31st, 31 more than during 1898, and 47 more than during 1897. Eighty-eight of the 489 deaths from consumption in the same city during 1897 were of patients who had contracted the disease in the State, 99 out of 505 deaths in 1898, and 58 in 1899.

A HOSPITAL IN NEED OF MONEY. — We are informed that the Hospital for Sick Children, London, the oldest institution of its kind in England, is urgently in need of money to continue its work. If aid is not forthcoming, the hospital must be closed. This is suggestive of the situation in England with regard to home charities, and the diversion of benevolence temporarily into other channels.

SMALL-POX IN MISSISSIPPI. — A violent outbreak of small-pox is reported from the Jonesville District, Miss. About 100 deaths occurred during a period of six weeks, and difficulty has been experienced in burying the dead. Medical attendance has been inadequate and the neighborhood is in a state of demoralization. Every effort is being made to check the spread of the disease.

PROFESSORSHIP OF MEDICINE IN EDINBURGH. — The professorship of medicine, or the practice of physic, in the University of Edinburgh, rendered vacant by the death of Sir Thomas Grainger Stewart, is said to be worth about £1,050 a year.

TYPHOID FEVER IN LADYSMITH. — Mr. Frederick Treves, surgeon of the British forces in South Africa, has reported that immediately after the relief of the town there were 800 cases of typhoid fever among the inhabitants.

BOSTON AND NEW ENGLAND.

ACUTE INFECTIOUS DISEASES IN BOSTON. — For the week ending at noon, March 14, 1900, there were reported to the Board of Health of Boston the following cases of acute infectious diseases: diphtheria 106, scarlatina 48, measles 70, typhoid fever 8.

TYPHOID FEVER AT HAVERHILL, MASS. — An epidemic of typhoid fever is reported from Haverhill. In the last few weeks many cases of the disease have appeared. In all there are 25 cases in the city, and all are confined to houses connected with the water supply of Kenoza Lake. The Board to-day made known their findings in the following communication to the Water Board. "It is the judgment of the Board of Health, after a careful investigation, that the present excessive sickness from typhoid fever is due to the pollution of the water supply coming from Kenoza Lake, and that the source of its special infection is the leaking cesspool connected with the Hale Hospital. Its contents are discharged on the surface of the ground, and have been carried by recent heavy rain storms and also by a system of stone drains, into an eight-inch Akron pipe for the removal of surface water from the street on the northerly side of Kenoza Ave. This pipe, passing under the roadbed, connects, presumably, as there is no other visible outlet to it, with an old stone drain, or covered water course, which discharges into an open trench about 150 feet distant, thence over the surface of the ground, about 200 feet into the northwesterly side of the Lake."

STATISTICS FROM NEWTON, MASS. — The number of cases of diphtheria in Newton decreased during the month of February. On the 1st of February the Board of Health had under observation 29, while in the mortality statistics for February there are only seven cases of diphtheria. During February there were 40 deaths, and the average death-rate per thousand for the month was 17.39, as against 17.83 last year. There are 19 cases of scarlet fever at present and 14 were reported during the month.

A BILL TO RESTRICT THE USE OF ARSENIC. — The Committee on Public Health of the Massachusetts Legislature has under consideration a bill to restrict the use of poison as a coloring matter. The bill is aimed at arsenic, and seeks to prevent the manufacture and sale of textile fabrics and papers containing that mineral. An exception is made of dress goods containing no more than one-tenth grain of arsenic to the square yard.

REMONSTRANTS AGAINST THE BILL TO RESTRICT VIVISECTION. — President Eliot and Bishop Lawrence appeared among others at the meeting on Tuesday before the Committee of the Massachusetts Legislature and spoke against the bill to restrict vivisection. Dr H. P. Bowditch opened for the remonstrants.

INFLUENZA IN BOSTON. — The death-rate during the past week has been unusually high, owing in part to the prevalence of influenza. Ten deaths attributable to influenza have occurred. There has been a considerable epidemic of the disease at the Long Island Hospital, Boston Harbor.

A MEASLES WARD NEEDED. — The attention of the public is being directed by the Trustees of the Boston City Hospital to the great need of a ward for measles in the Contagious or South Department of the Hospital.

NEW YORK.

A Veterinary School for New York. — At a meeting of the Council of the University of the City of New York, held March 5th, a memorial was framed requesting the State authorities to adopt the Veterinary Department of the University (the New York American Veterinary College), for the educatjon of veterinarians in the section of the State in which New York City is situated. That city, the memorial claimed, was better adapted to the successful maintenance of a veterinary school than any other locality, especially on account of the advantages which it afforded in the matter of anatomical and clinical study.

Shortening of Term of Service in the Philippines. — Dr. D. H. Morgan, of the United States Navy, now in New York, who recently arrived from Manila, has, by request, sent to the Navy Department in Washington a report in which he strongly recommends that the terms of service of officers and men in the naval service on duty in the Philippines shall be made two instead of three years. The climate there he regards as very enervating, and he has found that its effects are seriously felt in the second, rather than in the first year; so that the men cannot stand the strain of continuous service there.

United States Revolver Association. — The United States Revolver Association was organized on March 5th, when Dr. Reginald H. Sayre was elected President, and Dr. Calvin Thayer Adams a member of the Executive Committee. Dr. Sayre, who is inspector of carbine and pistol practice in Squadron A of the New York National Guard, has won a large number of trophies in various contests by his skill in marksmanship. The Association has decided to accept a challenge received from France, and it is expected that the match will be shot in May in this country and in Paris at the same time.

A Unique Claim. — A claim of $2,386, arising from the importation of small-pox into the State of New York by the Joshua Simpkins Opera Company, was filed at Albany on March 10th, by the city of Geneva. A mild epidemic of small-pox in that section originated with a member of the company, who was taken ill at Ithaca. The company went to Geneva, where its twenty-six members were placed on the steamer *Onondaga* and quarantined on Seneca Lake for several weeks. The city's claim is for the cost of the quarantine.

Bills Passed by the Assembly. — Other bills recently passed by the Assembly are Dr. Henry's bill to shorten the hours of drug clerks, which is said to be free from the objectionable features of the one with the same object in view passed by the Legislature last year; and a bill authorizing New York City to appropriate $50,000 to aid in the erection of a monument to martyrs who perished in the prison ships in New York Harbor during the Revolutionary War.

State Hospital for Crippled and Deformed Children. — On March 9th the Assembly passed a bill establishing the New York State Hospital for the Care of Crippled and Deformed Children, and appropriating $10,000 for the purpose. The incorporation of the institution, one of the directors of which is Jacob A. Riis, was approved by the State Board of Charities.

A Fatal Case of Pemphigus. — A fatal case of pemphigus was reported at Bellevue Hospital during the past week. The patient was a young man of twenty-four, and the diagnosis was vouched for by Dr. George T. Jackson, the well-known dermatologist. A death from this skin affection, except in the form incident to infantile syphilis, is so rare as to be almost unique.

Miscellany.

INFLUENZA AND PNEUMONIA IN NEW YORK.

Aside from pneumonia, there have been fewer deaths reported from influenza since January 1st than during the same period of 1899, but the number of deaths from pneumonia has been considerably greater. The following tables, taken from the records of vital statistics, show the number of deaths from influenza and from pneumonia, by weeks, in the two years:

Influenza.

1899.		1900.	
Week ending Jan. 7	74	Week ending Jan. 6	6
" " " 14	53	" " " 13	5
" " " 21	31	" " " 20	3
" " " 28	27	" " " 27	4
" " Feb. 4	16	" " Feb. 3	7
" " " 11	19	" " " 10	8
" " " 18	14	" " " 17	11
" " " 25	16	" " " 24	29
" " March 4	11	" " March 3	29

Pneumonia.

Week ending Jan. 7	182	Week ending Jan. 6	141
" " " 14	143	" " " 13	183
" " " 21	124	" " " 20	156
" " " 28	140	" " " 27	160
" " Feb. 4	124	" " Feb. 3	158
" " " 11	138	" " " 10	184
" " " 18	151	" " " 17	203
" " " 25	157	" " " 24	256
" " March 4	151	" " March 3	261

While the deaths from pneumonia reported during the week ending March 3d reached the extremely high figure of 261, the number of deaths from pulmonary tuberculosis was comparatively small for this season of the year, namely, 106. The general mortality in the city during the week named represented an annual death-rate of 26.76, against 20.26 for the corresponding week of 1899.

CHRISTIAN SCIENCE: A MENACE TO THE PUBLIC HEALTH.

In Maryland the Christian Scientists appeared before the Committee on Hygiene of the Legislature in opposition to the proposed bill regulating the practice of medicine. From a report of the proceedings we make a few excerpts concerning which comment is unnecessary:

Dr. Samuel T. Earle asked Mr. Hammond how he discriminated between infectious diseases and those that were not infectious. "The power of God," said Mr. Hammond, "is the same always. We do not believe in infectious diseases, and a person, if a Christian Scientist, could not contract such diseases." Dr. Earle asked whether the method of treatment would be altered for an infectious disease, and Mr. Hammond replied that it would not. Dr. Edward Brush said it was unnecessary to ask the gentleman any further questions, as he had practically admitted that he could bring a patient with the small-pox into a room with other persons, or send a child with scarlet fever to school.

Dr. Earle asked Mrs. Linscott how she could distinguish diphtheria from tonsillitis. Mrs. Linscott laughed heartily and said: "All diseases are the same to us, and we make no microscopic investigations; but I could easily distinguish." Dr. Earle insisted upon knowing by what means, and Mrs. Linscott remaining silent, Mr. Hammond answered in sonorous tone, "Through the power of Almighty God." Mrs. Linscott stated that in a community of 500 people, all of whom were Christian Scientists, such a thing as diphtheria would be impossible, and there would be no necessity for any health department, as the community would be exempt from disease.

Dr. Fulton said the course of medicine of the Scientists was two weeks, according to their own books. He read of a little child who had a terrific toothache and was so completely cured in one night by a Christian Science teacher that not only did the pain leave her, but the cavity in the tooth became filled up, and this was without any physical treatment. The Christian Scientists all exclaimed that this was perfectly true.

Another incident read by Dr. Fulton was to the effect that a lady who had been horribly burned was sufficiently improved to go out the day after the accident. Several of the delegation said they knew this lady.

Another article read referred to a schoolboy who could not do his fractions until aided by Christian Science, when they at once became easy.

Mrs. Linscott remarked to Dr. Fulton, "No wonder the power of God surprises you!"

Dr. Brush read a letter from a member of the Health Department in Buffalo, stating that the sect of Christian Scientists should be suppressed, as they were a menace to the public health.— *Philadelphia Medical Journal.*

PLAGUE AT MENGTSZ YUNNAN, CHINA.

FROM the *Journal of Tropical Medicine* we learn that, with the exception of 1899, plague has been epidemic in Mengtsz Yunnan (population 12,000) every year for the last thirty years, or since the Mahomedan rebellion. The disease ordinarily appears about June, and finishes early in August — practically the rainy season. The annual plague mortality in the town and surrounding villages would range from 300 to 1,400. In Mengtsz rats are phenomenally abundant. Strange to say, cats are very rare and are much valued, fetching high prices. The Chinese say the cats die of plague caught from the rats. As Chinese cities go, Mengtsz is clean. Every year, just before the outbreak of plague, all street rubbish is removed; domestic rubbish is stored in open places in the city and is removed at the same time. Rats dying of plague are a familiar sight. Very few women get the plague — hence the title "City of Widows" applied to Mengtsz. Possibly the comparative immunity of females depends on the careful bandaging of their feet, which in this way are protected from injury and the bites of insects. Many of the women have had several husbands, a most unusual thing in China.

Correspondence.

THE OLD ORDER CHANGES.

BOSTON, March 10, 1900.

MR. EDITOR: — At the meeting of the Boston Society for Medical Improvement the other night, as one listened to the discussion of methods of teaching medicine, to the able papers of Dr. Councilman and Dr. Burrell, and to the remarks of President Eliot and Messrs. Ames, Cannon and others, it was interesting to reflect how the old order changes, and how soon the new becomes the old.

For years those of us who teach have been striving to devise new methods of imparting knowledge. Here comes a young gentleman from the Medical School, who tells us that we must revert to the method of our grandfathers; that knowledge cannot be imparted to such advantage as it can be acquired by the individual through his own efforts, judiciously guided and aided; and the young gentleman is right.

In the earlier years of this century students attended on the practice of active physicians and studied their cases, and that method, modified to suit our present needs, is again the favorite one.

Of course, all that is good and true, as President Eliot so well said. As a section teacher myself, I have long appreciated the value of case study and individual instruction, and I feel that we are developing such lines of work to the great advantage of the student. But is it indeed true that the old-fashioned lecture was the futile thing Dr. Councilman and President Eliot tell us it was?

Between twelve and fifteen years ago I was a student in the Harvard Medical School. Many of my old teachers are still teaching there; many of them attended the meeting of which I write. Who am I, that I should rise up and tell them that their labors were a vain thing? That their strivings to impart knowledge were misdirected strivings, and that their words were as naught? Indeed, I am moved to say to those laborious men something very different, and, though we may have resurrected and perfected another thing, that thousands of us, taught largely on the old didactic plan, still look back on our pains as not altogether unfruitful.

To name names may seem invidious, but when I recall some of those charming, forceful, teeming lectures, I am inspired again. In both Harvard College and the Medical School were teachers whose class-rooms were crowded, whose discourses were eagerly anticipated. Who can regret the words of Mr. Norton and Mr. Shaler in Cambridge? Who failed gladly to attend the lectures of Dr. Bigelow, Dr. Cheever, Dr. Bowditch, Dr. W. L. Richardson, Dr. Francis Minot, and many others in Boston?

To such days, to such teaching and to such men we owe a debt, Mr. Editor, which we can never repay, and as we enter upon a field of new and perhaps more fruitful endeavor, let us not neglect to look backward for a moment, and gladly to render honor where honor is due.

Very truly yours,

J. G. MUMFORD, M.D.

THE DISCOVERY OF THE INFLUENZA BACILLUS.

BOSTON, March 10, 1900.

MR. EDITOR: — A correspondent in your issue of March 8th implies, but is cautious enough not to directly state, that the reviewer of a book on bacteriology in a recent number of the JOURNAL has made a mistake in pointing out that in this book, "Canon is erroneously credited with a part in the discovery of the bacillus of influenza." Your correspondent gives no basis for his idea, except that "In Berlin, in 1892, Canon was the flushed and happy recipient of congratulations for a discovery simultaneous with that of Pfeiffer." What are the facts? Canon did

announce simultaneously with Pfeiffer the discovery of the influenza bacillus. This organism Canon claimed to have found by careful searching of cover-glass preparations of drops of blood taken from the finger tip in a certain proportion of cases of influenza. He did not prove that all the bacteria seen by him were of the same kind, nor did he prove that any of these bacteria were identical with the bacillus discovered by Pfeiffer in the sputum, bronchi and lungs, in cases of influenza. Canon's work thus consists essentially in observations of bacteria in cover-glass preparations of the blood from the peripheral circulation. Such observations, however, are always open to the objections that the bacteria seen come from the staining solutions used, or from the skin, and unless they are confirmed by cultures and by reliable observers, they are never regarded by bacteriologists as of much value. An examination of Canon's paper upon this subject in *Virchow's Archiv*, Bd. cxxxi, Heft 3, 1893, fails to reveal any reason why his observations should not be open to the objections above mentioned. Moreover, neither Pfeiffer nor any other worker has since succeeded in finding the bacilli in the peripheral circulation. Therefore, it is altogether improbable that Canon had any of Pfeiffer's bacilli before him in his preparations, and he should not be mentioned as one of the discoverers of the bacillus of influenza.

Very truly yours,

J. H. WRIGHT, M.D.

RECORD OF MORTALITY

FOR THE WEEK ENDING SATURDAY, MARCH 3, 1900.

CITIES	Estimated population.	Reported deaths in each.	Deaths under five years.	Percentage of deaths from

Deaths reported 3,222; under five years of age 1,026; principal infectious diseases (small-pox, measles, diphtheria and croup, cerebrospinal meningitis, diarrheal diseases, whooping-cough, erysipelas, fevers and consumption) 610, acute lung diseases 785, consumption 315, diphtheria and croup 118, measles 52, whooping-cough 33, typhoid fever 32, scarlet fever 28, diarrheal diseases 19, erysipelas 15, cerebrospinal meningitis 8.

From whooping-cough New York 27, Philadelphia, Boston and Cambridge 2 each. From scarlet fever New York 23, Philadelphia 3, Boston 1. From diarrheal diseases New York 13, Pittsburg 2, Philadelphia, Washington and Lawrence 1 each. From erysipelas New York 12, Boston 3. From cerebrospinal meningitis New York 7, Worcester 1.

In the thirty-three greater towns of England and Wales, with an estimated population of 11,610,236, for the week ending February 24th, the death-rate was 24.2. Deaths reported 5,387: acute diseases of the respiratory organs (London) 485, whooping-cough 120, measles 115, diphtheria 92, fever 47, diarrhœa 40, scarlet fever 30.

The death-rates ranged from 9.9 in Croydon to 44.7 in Preston: Birmingham 22.7, Bradford 21.5, Cardiff 13.7, Gateshead 23.4, Huddersfield 21.5, Hull 22.3, Leeds 29.5, Liverpool 33.8, London 21.5, Manchester 34.7, Newcastle-on-Tyne 25.1, Nottingham 21.3, Plymouth 27.1, Salford 39.0, Sheffield 27.6, Sunderland 22.3.

METEOROLOGICAL RECORD

For the week ending February 24th, in Boston, according to observations furnished by Sergeant J. W. Smith, of the United States Signal Corps: —

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING MARCH 10, 1900.

J. C. WISE, medical director, commissioned medical director from February 7, 1900.

E. Z. DERR, medical inspector, commissioned medical inspector from February 7, 1900.

R. P. CHANDALL, surgeon, commissioned surgeon from September 24, 1899.

J. T. KENNEDY, assistant surgeon, appointed assistant surgeon.

G. E. H. HARMON, medical inspector, detached from the "Baltimore" and ordered to the "Oregon."

F. B. STEPHENSON, surgeon, detached from the "Oregon" and ordered to the "Baltimore."

W. B. GROVE, assistant surgeon, detached from the "Brooklyn" and ordered to the "Baltimore."

H. H. HAAS, assistant surgeon, detached from the "Baltimore" and ordered to such other duty as the commander-in-chief of the Asiatic station may assign.

J. C ROSENBLEUTH, passed assistant surgeon, detached from the Naval Recruiting Rendezvous, New Orleans, La., and ordered home and to wait orders.

F. E. MCCULLOGH, assistant surgeon, detached from the "Nero" when put out of commission, and ordered to temporary duty on the "Independence."

I. N. HURD, pharmacist, ordered to additional duty on the "Massasoit," Key West, Fla.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF COMMISSIONED AND NON-COMMISSIONED OFFICERS OF THE UNITED STATES MARINE-HOSPITAL SERVICE FOR THE SEVEN DAYS ENDING MARCH 8, 1900.

MEAD, F. W., surgeon. Upon expiration of leave of absence to proceed to New York, N. Y., and assume charge of the Purveying Depot during absence of Surgeon C. E. BANKS. March 3, 1900.

BANKS, C. E., surgeon. Granted leave of absence for seven days from March 6th. March 3, 1900.

KALLOCH, P. C., surgeon. To proceed to Mobile, Ala., for special temporary duty. March 7, 1900.

GLENNAN, A. H., surgeon. To proceed to San Francisco, Cal., for special temporary duty. March 8, 1900.

PERRY, T. B., passed assistant surgeon. To proceed to Atlanta and report to the Governor of Georgia for temporary duty. March 8, 1900.

GUITERAS, G. M., passed assistant surgeon. Relieved from duty at Matanzas and detailed as quarantine officer at the port of Cienfuegos, Cuba. March 5, 1900.

BROWN, B. W., passed assistant surgeon. Upon being relieved from duty at the Cape Fear Quarantine Station, to proceed to Cape Charles Quarantine and assume command of the Service. March 8, 1900.

CUMMING, H. S., passed assistant surgeon. To report at Washington, D. C., for special temporary duty. March 3, 1900.

VON EZDORF, R. H., assistant surgeon. Relieved from duty at Atlanta, Ga., and directed to rejoin station at New Orleans, La. March 8, 1900.

MCCLINTIC, T. B., assistant surgeon. Relieved from duty at Cape Charles Quarantine Station and directed to proceed to Cape Fear Quarantine, Southport, N. C., and assume command of the Service. March 8, 1900.

TROTTER, F. E., assistant surgeon. Relieved from duty at Havana and detailed as quarantine officer at the port of Matanzas, Cuba. March 5, 1900.

SCHERESCHEWSKY, J W., assistant surgeon. Relieved from duty at the Immigration Depot, New York, N. Y., and directed to proceed to Havana, Cuba, and report to Surgeon H. R. CARTER for duty. March 2, 1900.

LORD, C. E. D., assistant surgeon. Relieved from duty at the port of New York, N. Y. (Stapleton), and directed to report to Surgeon L. L. WILLIAMS, Immigration Depot, New York, for duty. March 2, 1900.

WILSON, R. L., assistant surgeon. Granted leave of absence for twenty-one days from June 14th. March 7, 1900.

BAILEY, C. W., acting assistant surgeon. Granted leave of absence for seven days. March 3, 1900.

BALLARD, J. C., acting assistant surgeon. Granted leave of absence for four days from April 17th. March 3, 1900.

SOCIETY NOTICES.

BOSTON SOCIETY FOR MEDICAL IMPROVEMENT. — A regular meeting of the Society will be held at the Medical Library, 19 Boylston Place, on Monday evening, March 19th, at 8 o'clock.

Dr. E. A. Codman will present "A Study of Cases of Colles's Fracture at the Massachusetts General Hospital since the Introduction of the X-ray." This paper will be illustrated by the lantern. The following gentlemen are prepared to take part in the discussion of the cases: Drs. F. H. Williams, Scudder, Conant, Cotton, Lund.

ARTHUR K. STONE, M.D., *Secretary*, 657 Boylston Street.

SUFFOLK DISTRICT MEDICAL SOCIETY. — The Section for Clinical Medicine, Pathology and Hygiene will hold its meeting at 19 Boylston Place, Wednesday, March 21, 1900, at 8 P. M.

At 8 o'clock: Dr. J. N. Coolidge will report "Two Cases of Diabetes Mellitus."

At 8.15 o'clock: Dr. E. G. Cutler will read a short paper entitled "A Form of Digitalis Free from Fat."

J. BERGEN OGDEN, M.D., *Secretary*,
Harvard Medical School, Boston.

MUTTER LECTURESHIP OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

The next course of ten lectures instituted by the late Prof. Thomas Dent Mütter, M.D., LL.D., on some "Point or Points in Surgical Pathology," will be delivered in the winter of 1902–1903 before the College of Physicians of Philadelphia.

The compensation is $600. The appointment is open to the profession at large. Applications, stating in full subjects of proposed lectures, must be made before October 1, 1900, to the Committee on the Mütter Museum.

JOHN H. BRINTON, M.D., *Chairman*,
Northeast Corner of Thirteenth and Locust Streets,
Philadelphia, Pa.

RECENT DEATHS.

HARRIET P. BILL, M.D., of New York City, died on Wednesday March 7th, in New Hampshire. Dr. Bill has been resident physician of the Sherborn Reformatory and of the Child Hospital on Staten Island. She was also, later, matron of the New York Nursery and Child Hospital. She was a woman of unusual mental attainments.

OLIVER PAYSON HUBBARD, professor emeritus of chemistry and pharmacy at Dartmouth College, died at his residence in New York City on March 9th, in his ninety-first year.

CHRISTOPHER PRINCE, M.D., formerly a prominent New York practitioner, died at his home at Irvington-on-the-Hudson, on March 5th, of pneumonia, at the age of seventy-six. He was born in Brooklyn, N. Y., in 1823. He studied medicine under the late Dr. Willard Parker, and was graduated from the College of Physicians and Surgeons, New York, in 1845. He practised for a number of years at Fort Hamilton, L. I., and afterwards removed to New York. He was appointed a police surgeon in 1872, and subsequently resigned this position to accept the surgeonship of the Fire Department. One of his daughters is the wife of Dr. George B. Fowler, recently a Commissioner of the Board of Health.

AARON E PECK, M.D., of Brooklyn, N. Y., died suddenly of pneumonia, resulting from influenza, on March 8th, in his sixty-sixth year. He was graduated from the College of Physicians and Surgeons, New York, in 1855.

CLARENCE EDWIN BEEBE, M.D., of New York, died on March 1st. He was born in Brooklyn, January 4, 1839. He was graduated from Yale University in 1871, and from the Medical Department of the University of the City of New York in 1873. For several years he was a surgeon in the Veteran Corps of the Seventh Regiment, New York National Guard.

FRANK WALKER GRAVES, M.D., M.M.S.S., died in Woburn, March 13, 1900, aged fifty-eight years. He was born in Concord, N. H., and received his medical degree from the University of Vermont. He served the community in various ways, as trustee for the Burbeen Free Lecture Fund, member of the Woburn School Board, and President of the Middlesex County Medical Society. When the Ancient and Honorable Artillery Company visited London three years ago Dr. Graves went as surgeon. He leaves a widow.

THE OPEN OR OPERATIVE TREATMENT OF FRESH FRACTURES; IS IT EVER JUSTIFIABLE?[1]

With an Analysis of the Results of the Present Methods of Treatment in One Hundred and Fifty-Three Fractures of the Lower Extremity.

BY CHARLES L. SCUDDER, M.D., BOSTON,

Surgeon to the Massachusetts General Hospital, Out-Patient Department; Assistant in Clinical and Operative Surgery, Harvard University.

In responding to the invitation of the chairman of the Surgical Section to introduce the discussion upon the open treatment of fractures, it occurred to me that no better introduction could be made than the presentation of the actual results which have followed the generally accepted methods of treating fractures of the lower extremity.

In order to intelligently discuss the wisdom of operative interference in closed fractures, it is necessary to have a clear notion of the results of the present method of treating fractures. No surgeon, excepting a hospital surgeon of long experience, can have a great knowledge of these end results, and ordinarily few men are sufficiently interested, even though the opportunity be present, to record and study these results in cases coming under their personal observation.

With the permission of the visiting surgeons of the Massachusetts General Hospital, I have obtained the results in fractures of the bones of the lower extremity, after varying periods of time have elapsed. I will briefly state the conclusions of this investigation. It must be constantly borne in mind that statistical tables of the kind here presented are of value just in proportion as one studies the individual units composing them.

FRACTURES OF THE HIP OR NECK OF THE FEMUR.

The treatment followed: If unimpacted, care was exercised that the impaction was undisturbed, and if impacted, a light weight traction was applied to the thigh. The leg, thigh and body were steadied in the recumbent position by a long outside splint. The patient was kept in bed, and after a few weeks was allowed up and about, walking by the aid of crutches.

There are 16 cases in this series of fractures of the hip. Seven were between forty-two and forty-seven years of age; the remaining nine cases (with two exceptions, adults, whose ages were not known) were over fifty years of age; three of these were sixty years or over. This, then, is an adult series. The age given is that at the time of the receipt of the injury. Most of these cases were primarily or secondarily unimpacted.

The results are known in all of these hip fractures from two and one-half to twenty-four and one-half years after the receipt of the accident. In three cases, which were thirty-nine, thirty-eight and twenty-six years old, respectively, the result as to usefulness is said to be perfect, with the exception that there is slight grating in the hip at times, aching in the hip in stormy weather, and shortening of an inch or more, causing a perceptible limp in the gait. Thirteen of the 16 cases have more or less impairment of the functions of the limb. Movements at the hip-joint are limited. There is a weakness of the limb, necessitating the use of a crutch in many instances. Eversion of the foot is observed. There is pain in the hip, which extends down the thigh, even to the sole of the foot. There is a very decided limp in many cases. There is pain in the hip at night when resting in bed; pain upon going up and down stairs, and in stooping and in stepping forward. There is undoubted rheumatism in many cases. Atrophy of the muscles of the thigh, buttock and calf of the injured side is noted. In practically all these 16 cases, followed carefully many years after the original injury, there is impairment of the hip, anatomically and functionally.

FRACTURES OF THE THIGH.

The treatment followed: Etherization. Adhesive-plaster extension; ham-splint, coaptation splint, long T outside splint; body swathe. Later, plaster-of-Paris spica from ankle to axilla; crutches.

There are 35 cases in this series. Thirteen of these cases reported for examination. Fourteen cases occurred in childhood, averaging seven and one-half years old. These childhood cases were examined from one and one-half to seven years after the accident. All have perfect functional results. Four cases complain of slight pain in the thigh occasionally; three of the four have a little stiffness of the knee, one and one-half, three and three and one-half years respectively after the accident. Sixteen cases occurred in adults from eighteen to forty-eight years of age. This group was seen from one to six years after the injury. Five have unqualifiedly perfect results, without pain and stiffness. The remaining 11 cases have limited motion at the knee-joint, aching in the thigh, pain after exercising, pain in wet weather, a weakness of the whole leg and a slight limp. Five cases occurred in old age, averaging fifty-eight years. This group was seen from two to six years subsequent to the injury. None have perfect results. There is one case of fibrous union with shortening; two must use a cane in walking. The knees are painful, and motion of the knee-joint is painful and limited. Swelling of the whole leg is not uncommonly seen, and pain in wet weather is of course an ordinary occurrence.

FRACTURES OF THE PATELLA.

The treatment followed: There are 51 cases in this series. Five were compound. Fifteen were operated by wiring the bone, suturing the capsule, by using Malgaigne's hooks, and by steel pins. Thirty-six were treated by the expectant method, that is, by elevation of the whole limb, immobilization of the knee-joint, straps about the fragments, local compression, and more or less prolonged immobilization.

These cases were examined from one and one-half to ten and one-half years after the accident. Of the 15 operated cases, seven (46 per cent.) are about as good as the well leg. Eight are not as good as the uninjured leg. Of the 36 cases treated expectantly, 16 (44 per cent.) were about as good as the well leg, and 20 were not as good as the well leg. All cases had some limitation of motion at the knee-joint. In some the knee cracks while walking, feels stiff, aches and

[1] Read at a meeting of the Surgical Section of the Suffolk District Medical Society, December 6, 1899.

burns; is weak; is troublesome while going up and down stairs; gives way unexpectedly, causing a fall. In some there is pain after unusual exertion and in damp weather, stepping up is difficult, kneeling is painful, stepping upon irregular surfaces is painful. In others running and jumping are impossible.

FRACTURES OF THE LEG.

The treatment followed: Invariably the leg, thigh and foot were placed upon a posterior wire splint and immobilized by side splint and straps. Later the leg was placed in a plaster-of-Paris splint extending above the knee, the patient moving about by the aid of crutches. These cases were seen from one year and five months to ten years after the accident happened. The average period was between four and five years. There were 35 cases of fracture of the leg. Under twenty years of age there were seven cases; between twenty and fifty years of age, 21 cases; fifty years of age and over, seven cases; this series is largely, therefore, of adults of middle age.

Of those twenty years of age and under, six were closed fractures and one was an open fracture. Five cases had as good a leg as before the injury; these were all closed fractures. Two cases had poorer legs than before the injury; one of these cases was open and one was closed. Of those twenty-one years to fifty years of age, 11 were closed fractures and 10 were open fractures. Eight cases had as good a leg as before the injury. Of these eight, five were closed and three were open fractures. Thirteen had poorer legs than before the injury. Of these 13, six were closed and seven were open fractures. Of those fifty years and over, four were closed and three were open fractures. All these cases had poorer legs than before the injury. Of the 35 cases of fracture of the leg, 21 were closed and 14 were open fractures. Of the 21 cases of closed fractures only eight (40 per cent.) were perfect results. Of the 14 cases of open fracture, only three (21 per cent.) were perfect results.

These cases invariably complain of flat-foot; pain in the fracture when the weather is damp; cramps at night in the calf of the leg; pain after long standing; a weakness of the leg; a swelling of the leg; pains through the leg after using it much; a stiffness of the ankle-joint; limitation of motion of the knee-joint; that stepping upon an uneven surface is troublesome; that the foot turns in; that there is a limp; of rheumatism.

Considering these groups of fractures of the lower extremity the results are unsatisfactory.

In the fracture of the hip[2] in old age the physical changes in the bone will always modify the reparative processes to some extent. Age symptoms will always appear. Eighty-one per cent. of the results are poor. Much can be attempted for these unfortunate people by more careful fixations and the operative treatment of pegging or clamping. In young adults with impaction and deformity the impaction should be broken up and the fracture set accurately.

In fracture of the thigh the apparent effect of age is seen in the end results obtained during the different periods of life. In childhood all fractures resulted in perfect functional results, 100 per cent. In adult life 31 per cent. were perfect, 69 per cent. imperfect. In old age none were perfect, 100 per cent. imperfect. These imperfect results of 69 per cent. and 100 per cent. can certainly be reduced.

In fracture of the patella statistics are misleading, for treatment of this fracture has so radically changed that cases are no longer to be fairly compared unless the method of treatment is known in all cases. To-day there are four methods of treating fracture of the patella:

(1) The old expectant method, by straps, immobilization, rest, no motion permitted at the knee for six months or more, unprotected.

(2) The new expectant method, which is the same as the old, with the addition of early continuous massage and early use of the limb.

(3) The old operation, by wiring with silver wire and long immobilization.

(4) The new operation, by repairing the bony damage and the damage to all the soft parts as well with early use and massage; very properly called the completed operation. The second and fourth methods of treatment are the most satisfactory. The results of these methods will be comparable.

In the series of cases of patellæ here reported 46 per cent. operated upon made a good recovery; 44 per cent. not operated upon made also a good recovery. Even in these cases which are said to have made a good recovery all exhibited limitation of motion at the knee-joint, in the extreme of flexion.

In the closed fracture of the leg 60 per cent. showed a poor result. In the open fracture of the leg 79 per cent. showed a poor result.

Very great care has been exercised in the preparation of the tables, which relate the details of each case in the several groups of fractures. A perusal of these cases thus tabulated will prove instructive.

Changes in the accepted methods of dealing with fractures of bone have been very gradual. Very little zeal has been exercised in dealing with simple fractures. Such fractures have been almost disregarded by surgeons in our large hospitals, the treatment of uncomplicated cases in hospital practice passing into the hands of the house surgeons, who ordinarily know little as to the detailed care of such so-called simple cases. Until recently, little clinical instruction has been given in the medical schools of this country upon the practical treatment of fractures.

The classical division of fractures into those in which there is a wound from the surface to the broken bone and those in which there is no such wound is still recognized as a fundamental division. The former group of compound fractures was invariably associated with various alarming conditions — namely, with primary or secondary hemorrhages, with suppuration, with sloughing of soft tissues, with necrosis of bone, with various forms of blood poisoning known to us under the names of sapremia, septicemia, pyemia, with hospital gangrene, with erysipelas, with greatly delayed union, and not very infrequently with amputation and death. The mortality from this group of fractures in the ordinary course of treatment in hospital practice was as high before the antiseptic period as 68 per cent., nearly 70 per cent. Is it any wonder that the fracture without an open wound of the soft parts resulting ordinarily in freedom from all infections and complications, resulting in safety to life, and in a more or less perfect recovery — is it any wonder that such a fracture should have been styled a simple fracture? Is it any wonder that the simple fract-

[2] These cases have been carefully treated. The present methods of treatment are faulty and can be improved.

ure was regarded as a *noli me tangere*, lest the simple should be converted into a dreaded compound fracture? This influence of pre-antiseptic days has been felt strongly up to the present time. The fear of suits for malpractice has likewise had its influence in hindering advance in the treatment of fractures and in encouraging surgeons to follow the old let-alone treatment.

The treatment of closed fractures has always been thought to be easy and simple. The tables are to-day being reversed; it is the simple fracture which to-day is found to be the most difficult to treat, if the problem of treatment is fairly faced. Is there anything more difficult to treat satisfactorily than the simple oblique fracture of both bones of the leg above the ankle; than fracture of the surgical neck of the humerus with or without displacement of the head of the bone; than fracture of the clavicle with considerable displacement? Is the separation of the upper epiphysis of the humerus an easy lesion to treat satisfactorily? Instances may be multiplied until it is evident that each bone is frequently fractured in a way most difficult for easy and satisfactory treatment by existing methods.

The Röntgen ray provides through the developed plate and fluoroscope accurate anatomical knowledge of the relative position of broken bones. The interpretation of the fracture seen through the fluoroscope and upon the plate must be made by one skilled in the art. The casual observer makes many errors in judgment and misinterprets the conditions present. The exact conditions of exposure and position under which the skiagraph is taken must be known before even the trained interpreter can correctly make the diagnosis. The x-ray provides the means for an accurate diagnosis.

Championnière, the one who has urged most strongly the use of massage in the treatment of fractures, finds that by it pain disappears, tension disappears with the absorption of ecchymosis, a sedative nervous effect is obtained, the callus forms more rapidly and consolidates earlier, function is restored to the part early, and that there is less atrophy of muscles, less stiffness of joints and tendons, less edema and a better local circulation. These assertions have been demonstrated to be true by men in this country, and the proper use of massage as a means to an end in the treatment of certain fractures is now thought to be desirable. It is to fractures near joints rather than to those in the diaphysis of the bone that massage is particularly applicable, and it is so used by the German surgeons. Massage properly applied will improve the ultimate results of fractures near to joints, under both the closed and open treatment. Massage has hitherto been used too little in the hospital treatment of fractures. It should be used systematically and its great benefits studied.

From analogy, considering the results of excisions of the knee-joint, an operation having to do with the larger bones of the leg by some method of internal and external fixation, we should expect good results in operations for fracture of the same bones. Excision of the knee is undertaken without fear of infection and with a strong probability of union taking place between the two bones. I find that of 13 excisions of the knee for tuberculosis the results, after from one to six years, showed solid union of the bones, with the exception of one case in which there was, after four years, very slight motion.

The mortality following compound fractures of the extremities has fallen from 68 per cent. a few years preceding the introduction of antiseptics, to two or three per cent. at the present time. Dennis has published a list of 1,000 consecutive cases of compound fractures treated in four metropolitan hospitals, with a mortality of one-seventh of one per cent. Practically, therefore, sepsis has been done away with in the treatment of compound fractures. In operations, therefore, upon closed fractures the element of sepsis may be left out of account in reckoning the risk of interference. I have found in six recently reported cases in which closed fractures have been treated by open incision no sepsis.

From analogy, osteotomy being a simple, safe and satisfactory surgical procedure, the operative treatment of closed fractures should be a safe procedure so far as the likelihood of infection is concerned. The only element not common to the two conditions is that of laceration of the soft parts in the case of fracture. The experience of those operating aseptically upon closed fractures demonstrates that this difference in the two conditions need not be regarded.

Very few are familiar with the conditions existing at the seat of fracture immediately after its occurrence. The denuded bone, comminuted fragments possibly, the great mass of blood clot from the torn vessels, the injury to the soft parts, often very extensive, far from the seat of the fracture of the bone, all these conditions if seen in a superficial wound or presented to the surgeon in an open fracture, would immediately receive attention. The fact that these conditions exist in every fracture to a greater or less degree should lead to their treatment in a rational way, by open incision.

The wound of the hard parts should be treated upon the same principles as the wound of the soft parts. There is as great safety to-day in an open as in a closed wound. There is greater safety in an open than in a closed fracture. Closed fractures of the vault of the skull are very generally operated on by surgeons to-day in the presence of cerebral symptoms, no matter how trivial.

Weir,[3] in a case of closed fracture of the malar bone, incised the mucous membrane above the canine tooth, opened the antrum, inserted a steel sound and lifted the depressed bone into place, packed the antrum with iodoform gauze, and the patient recovered without deformity.

Spencer[4] reports that Hearn has incised and sutured two fractures of the clavicle. In one case the subclavius muscle was caught between the fragments of the fracture, in the other case a triangular piece of bone was broken off and lay displaced between the fragments. The result in each instance was a perfectly shaped clavicle and a scarcely perceptible scar. At the Congress of French surgeons, Heydenreich did not favor operation upon the clavicle, unless a nerve or vessel were in danger. He objects to any scar and to the resulting swelling, which certainly did not appear in Hearn's cases.

McBurney,[5] Porter and others, have used the open method in fracture of the surgical neck of the humerus, with and without dislocation of the upper fragment.

Barker[6] has treated recent closed fractures of the

olecranon process of the ulna by incision and suture, with good results in all the cases.

Watson Cheyne [7] reports a partial fracture of the head of the radius in a girl twenty-six years of age. He removed the portion of the radial head fractured, with a perfect functional result. The portion of the head remaining intact prevented possible lateral motion at the elbow.

Wainwright [8] reports a fracture of the coronoid process of the ulna, together with a fracture of the radial head. He removed the head of the radius and a part of the coronoid of the ulna. This operation was followed by good functional results.

Watson Cheyne reports a fracture of great interest in a boy of thirteen, namely, a fracture of the olecranon and coronoid processes of the ulna, together with a fracture of the external condyle of the humerus. He wired the olecranon and removed the fragments of the coronoid and external condyle. Later it was necessary to remove the silver wire from the olecranon, because it pricked the skin and was an annoyance when the child moved his arm. The boy recovered with a useful arm.

Bruns and Poland, as early as 1884, recommended operation in recent epiphyseal separations, in cases in which the fragments are so locked together that they cannot be restored to their proper position, and when a fracture of the epiphysis extending into the neighboring joint is likely to interfere permanently with its normal function, and when a dislocation accompanies the separation which is impossible of reduction, and when the dislocation presses upon important structures, as often happens in separation of the lower femoral epiphysis.

Fractures of the femoral neck have been pegged by Cheyne and Senn [9] with successful results. Cheyne's case was instructive in that a woman with infantile paralysis in one leg fractured the other femoral neck. Cheyne pegged the fracture with an ivory peg and she made a splendid recovery.

Allis [10] has many times operated upon fracture of the femur, when in the upper one-third of the shaft, with good result. It should be generally recognized that many of these fractures cannot be set by traction or position, and that the only method that warrants a satisfactory result is that of the open treatment. Allis uses steel screws. The weakness of the fracture of the femoral shaft is probably due in large measure to the angular deformity and rotation of the upper fragment which result after the ordinary treatment.

Lane [11] advocates the open treatment in recent fractures of the leg in order that oblique fractures of the tibia and fibula near to the ankle may be held satisfactorily. Lane is especially interested in the relative position of the two fragments in a leg fracture. He maintains that the old-time and generally accepted method of placing the foot at a right angle, with the inner side of the great toe in a line from the anterior spine and mid-point of patella, results in permanent deformity of the leg.

Fractures of the patella have for some time been subjected to two distinct forms of treatment, either the expectant treatment or the open treatment by some form of suture. Good functional results are obtained by the expectant treatment, at the expense of time to the patient. Ultimate recovery is longer by this method. By the operative method a quicker result is obtained, and it is in many particulars better than that obtained by the expectant treatment.

The open treatment of the fracture should be undertaken only after careful consideration of the health of the patient, and under the most rigid antiseptic and aseptic conditions possible. The open treatment of the fracture should be carried out only by a skilled and competent surgeon. It should not be done in the aged. It is an operation for young adults, particularly for the laboring man. Early massage and passive and active motion after four weeks are desirable in the treatment of the fracture after operation.

The open method. — The operation should be performed only by skilled surgeons, as soon after the injury as is possible. It is thought by some that if it cannot be performed immediately following the injury that it should be done after about one week. Scrupulous antiseptic preparation of the skin throughout the whole circumference of the limb and for a long distance either side of the seat of the fracture is absolutely essential. This preparation should be that which the surgeon finds efficient preceding other operations. The skin incision should fall, when possible, away from the line of fracture, so that the wound of the soft parts shall not cross the wound of the bone. All bits of detached bone, fragments of muscle and all blood clots should be removed; all hemorrhage checked. When possible, the bones should be reduced without cutting the broken ends. For it is wise to lock the bones together in their natural and original position.

Fixation of the fragments. — Attempts have been made to fix the fragments of a fractured bone in different ways in the treatment of open fractures and in ununited fractures: Forms of suture and wrapping of fragments by silver wire, silk, silkworm gut and chromicized catgut; forms of pegs and screws of ivory and steel; forms of ferrules of bone; dovetailing fragments together; the Parkhill clamp, which inserted into the two fragments is allowed to project beyond the skin covering the broken bone.

It is impossible to determine which method of those in use to-day will prove effective until the fracture is exposed to view. That method in any given case is the best which preserves the alignement of the shafts of the bones.

The general condition of the patient must be carefully studied before deciding upon operation. In extreme age operation may be contraindicated because of insufficient kidneys. Some disease may be present contraindicating operative interference. Operations should not be done indiscriminately without regard to constitutional conditions.

Difficulties which hitherto have been concealed by an intact skin. — The difficulties of reducing fractures will become more and more apparent as the open treatment is more commonly used. It will be found that no one factor is the cause of the difficulty, but more often it is due to a shortening of all the soft parts of the limb about the fracture occasioned by hemorrhage into the tissues; by retraction of tissues, which have been normally stretched, and after the fracture have no resistance offered to their retraction. This difficulty in reduction I have found to be more common than is generally supposed. A recognition

of it as a cause will lead undoubtedly to the supplementing of splints by internal fixation in the treatment of many fractures.
